Left Atrial Appendage: Anatomy, Function, and Importance in Thrombus Formation

Infective Endocarditis In India: A Broad Picture Of A Very Large Country

My Approach to

My Approach to Imaging the Atrial Septal Defect by Three-Dimensional Echocardiography

My Approach to Echocardiography in Radiofrequency Ablation of Hypertrophic Obstructive Cardiomyopathy

My Approach to Transseptal Mitral Valve-In-Valve

What do Cardiologists Expect

What do Cardiologists Expect from the Echocardiogram in Heart Failure with Reduced Ejection Fraction?

Original Article

Left Atrial Function Analysis in Patients with Functional Mitral Regurgitation Associated with Dilated Cardiomyopathy

Left Ventricular Longitudinal Linear Displacement Versus Global Longitudinal Strain on Cardiovascular Magnetic Resonance

Is Paclitaxel Less Cardiotoxic in the Treatment of Breast Cancer Before or After Doxorubicin?

Review article

Assessing Myocardial Viability in Clinical Practice

Systematic Review Article

Role of Strain in the Early Diagnosis of Diabetic Cardiomyopathy

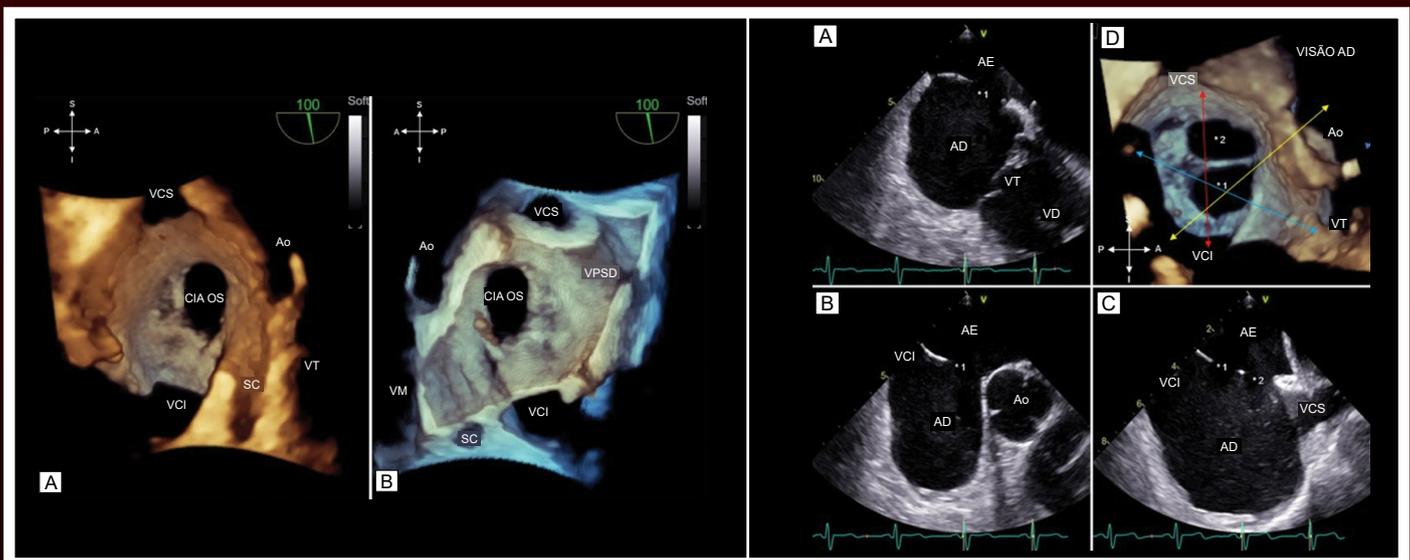

Case Reports

Late Presentation of COVID-19-Associated Transmural Myocardial Infarction with Non-Obstructive Coronary Atherosclerosis

Dilated Cardiomyopathy as Initial Presentation of Mucopolysaccharidosis in Infant

Diagnosis of Coronary Anomaly of the Circumflex Artery With Retroaortic Course by Transthoracic Echocardiography (Rac Sign) Confirmed by Computed Tomography Coronary Angiography: A Case Series

Primary Cardiac Lymphoma: Role of Imaging Multimodality in Diagnosis

Volume 35, Nº 2, April/May/June 2022

Left Atrial Appendage: Anatomy, Function, and Importance in Thrombus Formation

Apêndice Atrial Esquerdo: Anatomia, Função e Importância na Formação de Trombos

Taylla Mendes Silva, Gustavo Brandão de Oliveira, Thais Lins de Souza Barros, André Barbosa de Andrade, Bruno Bom Furlan, Maria do Carmo de Pereira Nunes

DOI: 10.47593/2675-312X/20223502eabc301

Infective Endocarditis In India: A Broad Picture Of A Very Large Country

Endocardite Infecçiosa na Índia: Um Panorama de um País Enorme

Ashish Agrawal, Shantanu P Sengupta

DOI: 10.47593/2675-312X/20223502eed_15

My Approach to - Como Eu Faço

My Approach to Imaging the Atrial Septal Defect by Three-Dimensional Echocardiography

Como Eu Faço Ecocardiograma na Ablação por Radiofrequência da Cardiomiopatia Hipertrófica Obstrutiva

Daniela Lago Kreuzig

DOI: 10.47593/2675-312X/20223502ecom32

My Approach to Echocardiography in Radiofrequency Ablation of Hypertrophic Obstructive Cardiomyopathy

Como Eu Faço Ecocardiograma na Ablação por Radiofrequência da Cardiomiopatia Hipertrófica Obstrutiva

Antonio Tito Paladino, Andrea de Andrade Vilela, Jorge Eduardo Assef, Bruno Pereira Valdigem

DOI: 10.47593/2675-312X/20223502ecom28

My Approach to Transseptal Mitral Valve-In-Valve

Como eu Faço Valve-in-Valve Mitral Via Transeptal

Andrea de Andrade Vilela, Maria Estefânia Bosco Otto, Antonio Tito Paladino F., Vanessa Andreoli Esmanhoto

DOI: 10.47593/2675-312X/20223502ecom24

What do Cardiologists Expect - O Que o Cardiologista Espera

What do Cardiologists Expect from the Echocardiogram in Heart Failure with Reduced Ejection Fraction?

O que o Cardiologista Espera do Ecocardiograma na Insuficiência Cardíaca com Fração de Ejeção Reduzida?

Ciro Mancilha Murad, Danilo Bora Moleta, Fabiana Goulart Marcondes-Braga

DOI: 10.47593/2675-312X/20223502ecard06

Original Article - Artigo Original

Left Atrial Function Analysis in Patients with Functional Mitral Regurgitation Associated with Dilated Cardiomyopathy

Análise da Função Atrial Esquerda em Pacientes com Insuficiência Mitral Funcional Associada à Miocardiopatia Dilatada

Stephanie Macedo Andrade, Rodrigo Bellio de Mattos Barretto, Francisco Thiago Tomaz de Sousa,

David Costa de Souza Le Bihan

DOI: 10.47593/2675-312X/20223502eabc281

Left Ventricular Longitudinal Linear Displacement Versus Global Longitudinal Strain on Cardiovascular Magnetic Resonance

Deslocamento Linear Longitudinal do Ventrículo Esquerdo Comparado ao Strain Longitudinal Global por Ressonância Magnética Cardiovascular

Rafael Almeida Fonseca, Sergio Marrone Ribeiro, Clerio Francisco de Azevedo Filho, Roney Sampaio,

Flávio Tarasoutchi, Carlos Eduardo Rochitte

DOI: 10.47593/2675-312X/20223502eabc304

ABC Imagem Cardiovascular

Is Paclitaxel Less Cardiotoxic in the Treatment of Breast Cancer Before or After Doxorubicin?

Qual Estratégia Terapêutica é Menos Cardiotoxic no Tratamento do Câncer De Mama: Uso de Paclitaxel Antes ou Depois da Doxorubicina?

André Luiz Cerqueira de Almeida, Edval Gomes dos Santos Júnior, Aluísio José de Oliveira Monteiro Neto, Thyago Monteiro do Espírito Santo, Paulo André A. Almeida, Samuel Oliveira Affonseca, Caroline de Souza Almeida, Matheus Pamponet Freitas, Cecília Lopes Viana Santos, Vitória Régia Beserra Barbosa Ximenes, Mariana Andrade Falcão, Israel Costa Reis, Suzane Pereira de Souza, Maurício Gomes da Silva Serra, Ana Beatriz Menezes de Oliveira, Tayla Silva Santos, Nilson Lima Lopes, Marcelo Dantas Tavares de Melo
DOI: 10.47593/2675-312X/20223502eabc289

Review article - Artigo de Revisão

Assessing Myocardial Viability in Clinical Practice

Viabilidade Miocárdica na Prática Clínica

Miriana Basso Gomes

DOI: 10.47593/2675-312X/20223502eabc264

Systematic Review Article - Artigo de Revisão Sistemática

Role of Strain in the Early Diagnosis of Diabetic Cardiomyopathy

Papel do Strain no Diagnóstico Precoce da Cardiomiopatia Diabética

Thais Rossoni Weber da Silva, Roberto Léo da Silva, Adriana Ferraz Martins, Jefferson Luiz Brum Marques

DOI: 10.47593/2675-312X/20223502eabc293

Case Reports - Relatos de Caso

Late Presentation of COVID-19-Associated Transmural Myocardial Infarction with Non-Obstructive Coronary Atherosclerosis

Apresentação Tardia de Infarto Agudo do Miocárdio Transmural Sem Obstrução Coronariana Aterosclerótica Associado à COVID-19

Jaime Paula Pessoa Linhares Filho, Matheus Cardoso de Aragão, João Bosco Breckenfeld Bastos Filho, Ricardo Paulo de Souza Rocha, Fábio Holanda Lacerda, Francisco de Assis Carvalho de Santana

DOI: 10.47593/2675-312X/20223502eabc290

Dilated Cardiomyopathy as Initial Presentation of Mucopolysaccharidosis in Infant

Cardiomiopatia Dilatada em Lactente como Apresentação Inicial de Mucopolissacaridose

Ludimila dos Anjos Teixeira Romão, Fátima Derlene da Rocha Araújo, Camila Magalhães Silva,

Rodrigo Rezende Arantes, Zilda Maria Alves Meira

DOI: 10.47593/2675-312X/20223502eabc255

Diagnosis of Coronary Anomaly of the Circumflex Artery With Retroaortic Course by Transthoracic Echocardiography (Rac Sign) Confirmed by Computed Tomography

Coronary Angiography: A Case Series

Diagnóstico de Anomalia Coronariana da Artéria Circunflexa com Trajeto Retroaórtico por meio do Ecocardiograma Transtorácico (RAC Sign) e Confirmação pela Angiotomografia de Artérias Coronárias: Série de Casos

Raul Serra Valério, Alfredo A. Eyer Rodrigues, Carlos Eduardo Suaide Silva, Marly Uellendahl MD,

Introduction

The left atrial appendage (LAA) is an extension of the left atrium (LA) and has complex anatomical structure and unique pathophysiological properties. The LAA functions as a decompression chamber during left ventricular (LV) systole and under increased left atrial pressure conditions. Despite previously being considered a relatively insignificant portion of the cardiac anatomy, the LAA has been highlighted as an important structure involved in the genesis of thrombus formation and thromboembolic events. With the recent development of percutaneous closure devices, LAA morphology assessments have become increasingly important. This article aims to describe LAA anatomy and morphology, function assessment parameters, thrombus diagnostic challenges, and the main imaging modalities, particularly transesophageal echocardiography.

LAA anatomy

The LAA is a long, thin tubular structure with a narrow base that originates from the LA body (Figure 1).¹ Macroscopically, the LAA is visualized at the left border of the heart between the LV and the pulmonary veins.^{2,3} It commonly extends between the anterior and lateral LA walls. Its tip can be variously positioned, most commonly being in the anterosuperior direction and overlapping the left border of the right ventricular outflow tract or the pulmonary trunk and the main branch of the left coronary artery and the circumflex artery, but it can also be in the lateral or posterior direction, reaching the transverse sinus of the pericardium in some patients.² Anatomically, the superior portion of the LAA is closely related to the pulmonary artery, while its inferior portion is close to the free LV wall.⁴

The LAA ostium (LAAO) is separated from the left pulmonary vein orifices by the left lateral crest.⁵ On the other side, the smooth LA wall separates the LAAO from the mitral annulus.² A narrowing that marks the orifice of the appendix is visualized in the transition between the smooth LA

endocardium and the wrinkled LAA surface. Morphologically, the LAAO can be elliptical (68.9%), while its long axis is usually oriented obliquely to the mitral annulus in a foot-like (10%), triangular (7.7%), or round (5.7%) shape.⁶⁻⁸

The LAA passes through a narrowed region before its body opens up.² In this region, one to four lobes can be observed, and a multilobulated LAA (with two or more lobes) was seen in 80% of patients in a relevant study by Veinot JP et al. of 500 postmortem hearts.⁹ That study reported the frequency of one, two, three, and four lobes as 20%, 54%, 23%, and 3%, respectively, not corroborating a more recent postmortem study in which two lobes were observed in 64.3% and three lobes in 35.7% of specimens.⁸ The quantification of the number of lobes is important because a greater number of lobes is associated with the presence of thrombus regardless of clinical risk and blood stasis.^{10,11}

The LAA presents great anatomical diversity. Wang et al.⁷ established the classification used to categorize four morphological types, with the “chicken-wing” shape being the most common (48%), followed by the “cactus” (30%), “windsock” (19%), and “cauliflower” (3%) shapes.¹² These categories are related to the risk of clot formation, with the cauliflower shape being apparently more associated with embolic events.¹² This morphology is also associated with lower blood flow velocity,¹ a greater predisposition to blood stasis, while the chicken-wing shape is associated with a lower risk.¹³ A Czech study by Stefan et al. related the cauliflower and chicken-wing shapes with a higher risk of silent cerebral ischemia.¹⁴ However, this classification is limited by its subjective and observer-dependent nature as well as the possibility of overlapping morphologies according to viewing angle.^{2,15} Other factors also influence the risk of thromboembolic events,^{16,17} including a smaller orifice diameter, higher number of trabeculations,¹⁸ and higher number of lobes.¹⁰ Another study¹¹ highlighted that number and size of lobes and their orifices may be more important factors in risk of thromboembolic events than LAA shape.

Unlike the LA, whose wall is smooth, the internal LAA surface is trabecular, presenting muscle bundles⁹ called pectineal muscles that form complex indentations (Figure 1). These muscle bundles resemble feather- or fan-shaped palm leaves.¹⁹ Larger muscle groups can be confused with thrombi or intra-atrial masses.⁹ The LAA also presents great size variability by sex (greater in men), age (growing about 0.20 cm³ per decade),²⁰ and the presence of atrial fibrillation.

Images acquired in collaboration with anatomopathologist Geraldo Brasileiro Filho.

Figure 1 – Macroscopical view of the LAA. Images made from explanted hearts showing the external and internal aspect of the LAA. (A) External view of a one-lobe appendage. (B) Internal view of a one-lobe appendage. (C) External view of a multilobed appendage. (D) Internal view of a multilobed appendage.

LAA dimensions are significantly more voluminous and have larger orifices in patients with atrial fibrillation than in those with sinus rhythm.

LAA function

The LAA has both mechanical and endocrine functions.²¹ Its compliance is greater than that of the rest of the atrium; therefore, it can modulate the pressure in the chamber and compensate for volume overloads and pressure increases. In addition, the appendix has the highest concentration of atrial natriuretic peptide (ANP) granules in the LA (about 30%).^{4,22,23} Cardiomyocyte distention stimulates ANP secretion; therefore, as it is more compliant and concentrates the largest amount of ANP, the LAA is more sensitive to volume and pressure changes and has greater control of decreased blood pressures and increased heart rate, diuresis, and natriuresis.^{4,23,24}

The LAA performs active contraction,⁴ and its flow velocity can be quantified by pulsed Doppler. In most patients undergoing transesophageal echocardiography (TEE), this is a four-phase flow (Figure 2).^{4,25,26} The first wave corresponds to the outflow caused by appendage contraction at the end of ventricular diastole. The second wave represents the antegrade LAA filling flow during atrial diastole. The third wave has positive and negative components that reflect the mechanical waves at ventricular end systole (in this phase, numerous patterns of low-amplitude positive and negative waves are described).²⁶ And finally, outflow from the LAA occurs during the rapid ventricular filling phase. The decreased flow velocity in the LAA relates to the presence of spontaneous contrast (SC), sludge, and thrombus.^{21,25,27}

LAA function can be assessed by several parameters. LAA filling and emptying velocities by pulsed Doppler express the

LAA contractile function. In addition, LAA area, volume, and ejection fraction measurements by different methods reflect LAA function.

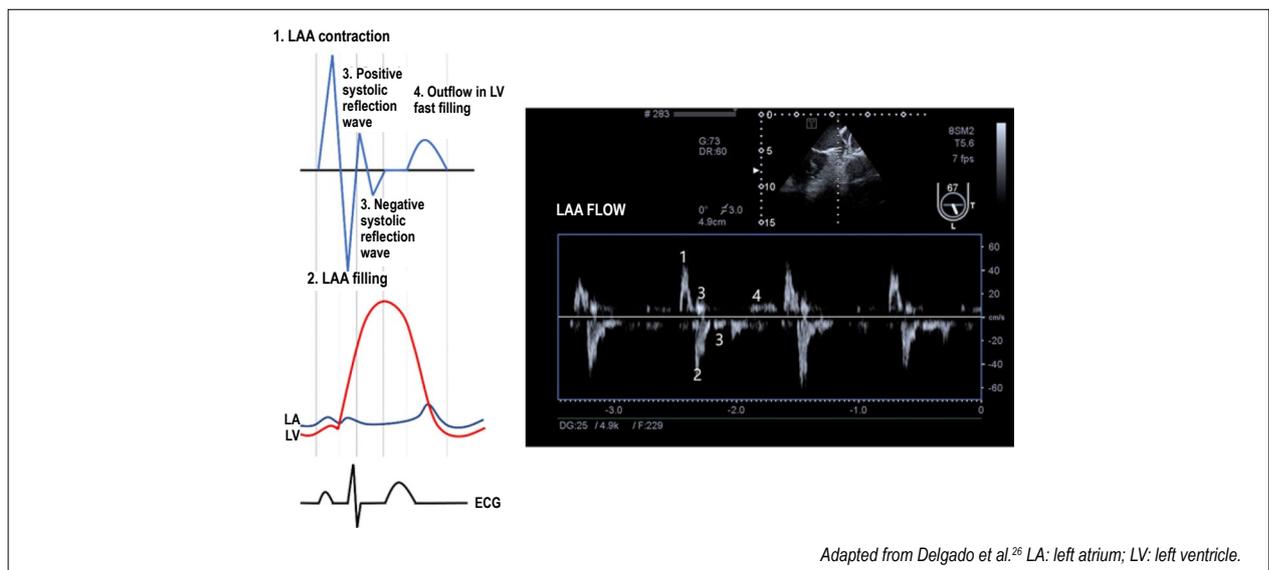

Blood stasis and thrombus formation

LAA contractility changes can lead to thrombus formation and subsequent thromboembolic events²⁷ regardless of the presence of atrial fibrillation (AF). AF generally presents with decreased LAA contractility, decreased blood flow velocities, and LAA dilation.^{28,29} The AF-related remodeling process makes the LAA function a static pocket, resulting in stagnation and thrombosis.

Approximately 75% of patients with cardioembolic episodes are estimated to have emboli arising from the LAA. LAA thrombi are present in up to 14% of patients with acute AF (<3 days).³⁰ Thrombus formation can develop even in AF patients receiving therapeutic anticoagulation therapy. A previous study showed that 1.6% of patients treated with anticoagulants for 1 month had echocardiographic evidence of a thrombus in the LAA.³¹

Limited data suggest that LV failure and increased LV end-diastolic pressure may also be risk factors for LAA thrombus in the absence of AF. Vigna et al.³⁶ identified LAA thrombi in eight of 58 patients with dilated cardiomyopathy and sinus rhythm. Consequently, the risk of thrombus formation in the LAA appears to be related to LAA dysfunction resulting from increased filling pressures regardless of cause.

The complex interaction of atrial endothelium, blood constituents, and blood stasis (i.e., the components of Virchow's triad) results in the formation of activated platelet aggregates and leukocytes³² or fibrinogen-mediated erythrocyte aggregates^{33,34} that present as spontaneous dense echocardiographic contrast or "smoke." These aggregates can progress to sludge and, eventually, thrombus.^{2,35}

Adapted from Delgado et al.²⁶ LA: left atrium; LV: left ventricle.

Figure 2 – Comparison between the flow pattern in the LAA in sinus rhythm, the cardiac cycle, and the electrocardiogram (ECG).

Imaging methods for assessing the LAA

Transesophageal echocardiography

TEE is the method of choice for studying LAA anatomy and function. Its sensitivity and specificity for detecting LAA thrombi compared to those observed intraoperatively are 92% and 98%, respectively,^{2,37,38} with negative and positive predictive values of 100% and 86%, respectively³⁸. The absence of a thrombus confirms that it is safe to proceed with cardioversion, with a low rate of thromboembolic events (0–0.8%) in adequately anticoagulated patients.^{39,40}

A complete LAA assessment should include LA, LV, and mitral valve imaging associated with a detailed assessment of LAA morphology, contraction, and flow velocities using two- and three-dimensional (3D) echocardiography.² LAA assessments can be started using a four-chamber section; however, as it is a lateral structure, the probe must be rotated counterclockwise and flexed to bring it to the center of the screen. Also, using a two-chamber section, the LAA can be zoomed or screen depth can be reduced to increase assessment accuracy.⁴¹ Two-dimensional TEE provides excellent LA and LAA characterization due to the anatomical proximity of these structures to the esophagus. Despite the LAA being a narrow tubular structure with a complex anatomy, thrombi within it can be identified with satisfactory accuracy by TEE. However, assessment sensitivity decreases in cases of small thrombi or those located within a lateral lobe.

Functional Doppler assessment is routinely used to improve LAA analyses (Figure 3). The pulsed Doppler should be placed at 1–2 cm from the LAAO. LAA flow velocity measured by pulsed Doppler is an indicator of risk of thrombus formation (risk increases as velocity decreases).² Velocities < 40 cm/s are associated with an increased risk of stroke and the presence of SC,⁴² with decreasing velocities of <20 cm/s being associated with thrombi in the LAA and a higher

incidence of thromboembolic events.^{43–47} Velocities < 40 cm/s require meticulous LAA assessments before cardioversion or interventions involving the LA and LAA.

LA thrombus is defined as an echogenic mass in the LAA or LA distinct from the LA endocardium or pectineal muscles (Figure 4).³⁸ Several differential diagnoses and thrombi misinterpretations should be considered, including acoustic shadowing of the ligament of Marshall, pectineal muscles, or non-differentiation of sludge and dense spontaneous echogenic contrast.^{2,48}

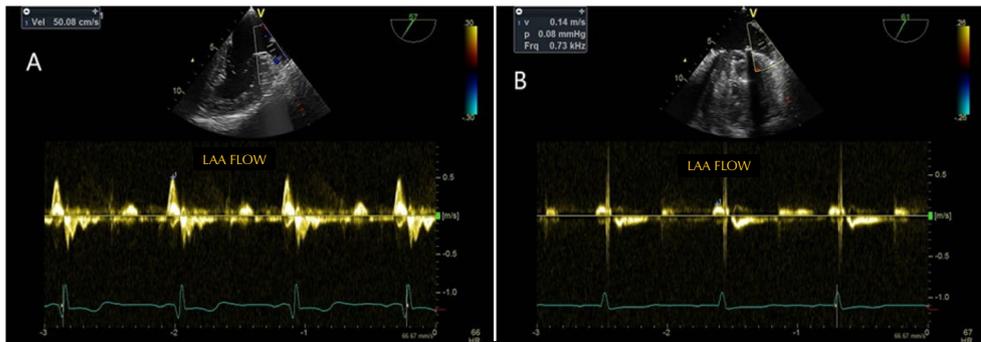

In cases in which the LAA images are suboptimal, ultrasound contrast agents help improve LAA visualization. The use of contrast eliminates many artifacts and usually demonstrates complete LAA opacification or filling defects.^{49,50}

LAA echocardiographic imaging is operator-dependent and, therefore, has a learning curve. Interobserver variability is an important limitation of this investigation since interobserver disagreement rates can reach 22% in the diagnosis of thrombus.

Challenges in diagnosing LAA thrombus

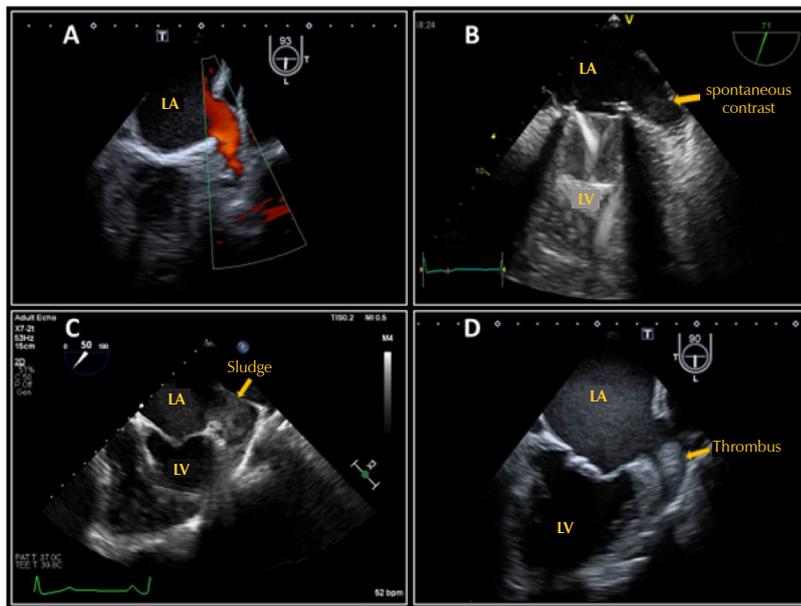

Echocardiographic evaluation of the LAA requires careful analysis by the echocardiographer. In some situations, LAA imaging misinterpretations can lead to hasty decisions. Exuberant pectineal musculature or appendage lobes can be interpreted as thrombi, thereby resulting in the use of unnecessary anticoagulant therapy (Figure 5). Thrombus misdiagnosis also leads to suspended percutaneous procedures, such as LAA, patent foramen ovale, and atrial septal defect occlusion, MitraClip implantation, AF ablation, and mitral valvuloplasty with a balloon catheter. Such procedures involve manipulation of catheters inside the atria and, consequently, increase the risk of embolization.

Ruling out LAA thrombi using TEE may enable early and safe cardioversion without the need for prolonged

AAE: apêndice atrial esquerdo.

Figure 3 – TEE demonstrating in (A) the normal velocity (50 cm/s) flow in the LAA of a patient in sinus rhythm, with an LA of normal dimensions and without the presence of SC. In (B), the reduced velocity (14 cm/s) flow in the LAA of a patient in the postoperative period of mitral valve replacement (mechanical prosthesis), in sinus rhythm, with dilated LA and presence of SC in the LAA.

LV: left ventricle. LA: left atrium.

Figure 4 – TEE showing the LAA filled in by color Doppler in image A. Images B and C show the presence of SC (B) and sludge (C) inside the LAA, respectively. In image D, the arrow indicates a thrombus in the LAA and the presence of SC in the LA.

previous anticoagulation.^{38,51} Thrombi within the LAA must be differentiated from the pectineal muscles, reverberation artifact originating from the coumadin ridge, septa between multiple lobes,⁵² SC, and sludge.

Thrombi are often located at the distal end of the LAA, almost always confined to its lumen and adherent to its walls. They have independent movement and echogenicity patterns as well as uniform consistency and textures that differ from those of the LAA wall. Their morphology varies, but they are generally rounded (Figure 4). They are often associated with the presence of SC within the LA.

Reverberation artifacts are also found within the LAA, being located at a position twice the distance from the transducer to the coumadin ridge. Its mobility totally depends on the coumadin crest movement. Its morphology is compatible with that of the object or structure that causes the artifact and is not related to the presence of SC in the LA. Reducing gain and using other imaging planes are strategies that the echocardiographer can use to avoid artifact formation. On the other hand, the stepped appearance and the position at a doubled distance reinforce the presence of a reverberation artifact inside the LAA. The echocardiographer should be

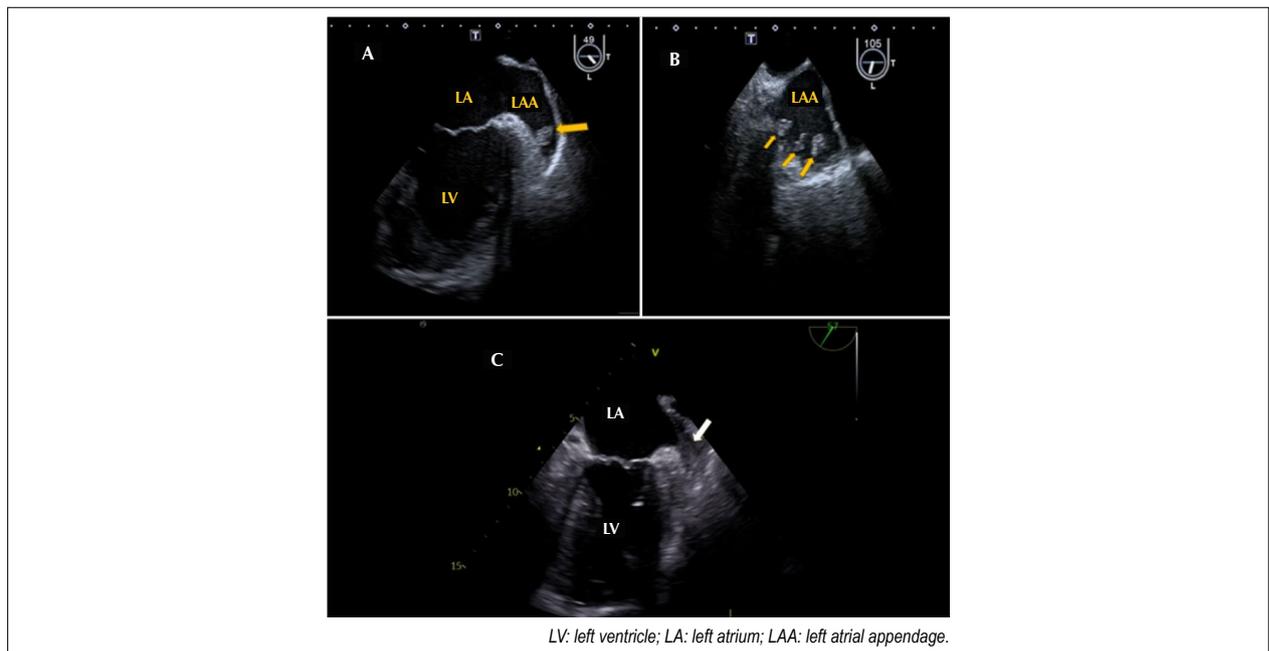

Figure 5 – Mid-esophageal slice TEE at 50° showing a mass within the LAA that can be easily interpreted as a thrombus (arrow) (A). Image of the same patient at 105°, clarifying that the mass is probably the three LAA lobes (B). Image C shows a reverberation artifact (arrow) produced by the coumadin ridge and visualized inside the LAA.

aware of the presence of a prominent coumadin ridge, which can also be misdiagnosed as a thrombus.

The pectineal muscles, in turn, are confined to the body of the LAA. Their mobility follows LAA movement, and they have identical echogenicity to that of the LAA wall. They are not related to the presence of SC.

SC, also known as smoke, is a swirling mist of varying density that reflects the low blood flow velocity (Figure 4).⁵³ It can be classified into four groups (1 to 4) by intensity, location, and presence of a vortex (movement) as proposed by Fatkin et al.⁴² (Table 1). However, SC quantification in clinical practice is difficult and depends on image quality, gain settings, and operator experience.

SC is reportedly noted in up to 60% of patients with AF.⁵⁴ Aspirin and warfarin therapy does not appear to affect the presence of SC in the LA.⁵⁵ Although patients with dense SC visualized in the LAA have a stroke rate of 18.2% per year if not treated with warfarin and a risk of stroke of 4.5% per year despite dose-adjusted warfarin, the presence of an LAA thrombus triples the overall rate of stroke.⁴⁰

Sludge, a dynamic fluid of gelatinous echogenicity with no well-defined mass, is present throughout the cardiac cycle.⁴⁸ It is often difficult to differentiate between sludge and thrombus. Sludge represents a stage after SC prior to thrombus formation that may have prognostic significance.⁵⁶

Other imaging methods for assessing LAA

Transthoracic echocardiography

Transthoracic echocardiography (TTE) has a limited capacity to identify or exclude thrombi in the LA and LAA,

with a reported sensitivity of 40–60%, mainly due to poor visualization of the LAA, where most atrial thrombi are located (Figure 6). In this sense, the use of harmonic images and the administration of ultrasound contrast agents can increase its ability to detect intracavitary thrombi.^{37,38,48}

Contrast echocardiography

Since the late 1990s, ultrasound contrast agents have been administered to improve the visualization of endocardial borders, including an improved LAA assessment. Recent studies of LA and LAA enhanced interrogation techniques reported statistically significant improvements in dimensional measurements and emptying characteristics. In cases of suboptimal LAA images, contrast agents help improve LAA visualization, eliminate artifacts, and reveal body filling defects.^{2,57}

Contrast agents improve the delineation of cardiac chamber endocardial borders, but their use has not been implemented in clinical routine to detect or exclude thrombi. Several reasons explain this circumstance, such as the use of predictive markers of thrombus formation such as pulsed Doppler of LAA blood flow and SC assessments; the low prevalence of thrombus in the LAA (5–13% in patients with AF but without therapeutic anticoagulation); and the even lower risk of an embolic event. In addition, the use of ultrasound contrast increases the time required to perform the test as well as its cost.^{48,58}

The ability of the contrast agent to completely opacify the LAA even in the presence of artifacts during native imaging minimizes the false identification of thrombi and allows the delineation of atrial thrombi, reducing the amount of inconclusive TEE and improving the echocardiographer's degree of interpretive

Table 1 - Classification of spontaneous contrast as proposed by Fatkin et al.

Grade	SEC	Description
0	None	Absence of echogenicity
1+	Mild	Minimal echogenicity located in the LAA or sparsely distributed in the LA main cavity that may be only transiently detectable during the cardiac cycle
2+	Mild to moderate	Swirling pattern denser than 1+ but similarly distributed, detectable without increased gain settings
3+	Moderate	Moderate and dense swirl in the LAA usually associated with lower intensity in the main cavity; may fluctuate in intensity but is constantly detectable throughout the cardiac cycle
4+	Intense	Intense echogenicity and very slow swirl patterns in the LAA, often with similar density in the main cavity
Sludge	Intense	Prethrombotic state can be defined as gelatinous echogenicity without a well-defined mass; present throughout the cardiac cycle

SEC, spontaneous echogenic contrast.

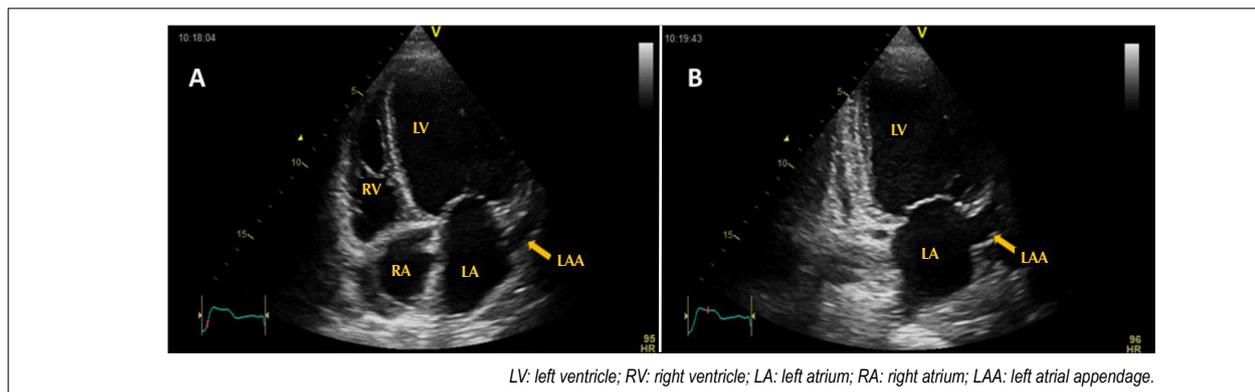

Figure 6 – TTE showing the LAA in apical four-chamber (A) and two-chamber view (B).

confidence. However, in cases in which non-contrast images are diagnostic and in the absence of SC evidence, the use of contrast fails to improve diagnostic confidence.^{50,57}

Three-dimensional echocardiography

The development of 3D TEE improves the ability to assess the LAA, allowing a selective perspective of its anatomy and better discrimination between artifacts, masses, and thrombi (Figure 7). The 3D method allows a more comprehensive assessment of multiple LAA lobes, which can be located in different planes, as well as a more accurate estimate of its geometry, size, and function with better distinction between pectineal muscles and thrombi.²⁶

Data remain limited regarding the sensitivity and specificity of 3D TEE for thrombus detection in the LAA. However, with recent advances in percutaneous device therapy for LAA closure, 3D TEE has become important for planning and guiding interventions.²

Intracardiac echocardiography

Intracardiac echocardiography (ICE) is an alternative imaging method when TEE is unavailable or inconclusive. ICE can provide multiple views and detailed LAA images to enable the reliable diagnosis of the presence of thrombus.³

Although it is less sensitive than TEE for thrombus detection, it can be a complementary method, especially when TEE

findings require further assessment. However, as an invasive procedure, its use in daily practice is limited, being primarily reserved for the cardiac catheterization laboratory during planned interventional procedures.²

Computed tomography

Computed tomography (CT) can identify LAA thrombi with good sensitivity and moderate specificity. Recent studies have concluded that LA and LAA thrombus analysis with isolated multislice CT is probably sufficient and non-inferior to TEE in patients with paroxysmal AF and normal systolic function.⁷ However, CT is not currently recommended for identifying thrombi in the LA and LAA (Figure 8).^{11–13,43}

CT generates 3D volumetric data of the heart, which can be reconstructed across different cardiac planes and phases to provide an accurate assessment of LAA anatomy with high spatial and temporal resolution and quantitative assessment.^{2,3} However, CT is not highly specific for the presence of a thrombus and, therefore, the high rate of false-positive results, together with the use of radiation and iodine-based contrast media, are the main limitations for its widespread use.

Cardiac magnetic resonance imaging

Cardiac magnetic resonance imaging (CMRI) is the main imaging method for evaluating cardiac masses.² Several imaging techniques provide relevant information about the

histological components and vascularization of the masses that, together with clinical data, can help distinguish between benign and malignant neoplastic masses, non-neoplastic masses (thrombi and cysts), or other structures.²⁶

Intracavitary thrombus is the most common non-neoplastic mass, and its appearance on CMRI depends on the time of their formation. In more acute cases, in which the thrombus has a large amount of oxyhemoglobin, the thrombi tend to appear with increased signaling on T1- and T2-weighted sequences. Subacute cases present hypersignaling on T1 and low signal intensity on T2 due to the paramagnetic effects of methemoglobin. In chronic cases, the thrombus is water-depleted and cellular debris is replaced by fibrous tissue, thus leading to low signaling on T1 and T2.

The paramagnetic contrast agent has an important role in aiding tissue differentiation between thrombi and tumors. First-pass perfusion imaging allows a clear distinction between the thrombus and the adjacent myocardium since the thrombus is an avascular structure and classically does not absorb the contrast medium. In addition, late gadolinium enhancement can quantify atrial fibrosis, which is independently associated with the presence of

thrombus in the LAA and SC and may be an additional risk stratification method.

However, CMRI has been evaluated in a limited number of studies, and its sensitivity and specificity for identifying LAA thrombus are similar to those of CT with high agreement with those of TEE. Thus, despite the evident advantages of CMRI, limitations remain to its widespread use in clinical practice, and it is not the recommended imaging modality for assessing thrombi in the LA or LAA.

Conclusions

The LAA, a complex structure with variable anatomy, constitutes the most common site of thrombus formation in the context of non-valvular AF. LAA function plays an important role in blood flow stasis and the risk of thrombus formation with subsequent thromboembolic events. TEE is the imaging modality of choice in LAA assessments, with high accuracy for detecting thrombi. Current and emerging transcatheter therapies, especially the implantation of LAA occlusion and exclusion devices, have further highlighted the importance of understanding LAA anatomy and function in clinical practice.

Infective Endocarditis In India: A Broad Picture Of A Very Large Country

Endocardite Infecçiosa na Índia: Um Panorama de um País Enorme

Ashish Agrawal¹, Shantanu P Sengupta²

Korba Diabetic & Cardio Center Korba,¹ Sengupta Hospital & Research Institute,² Nagpur, Índia.

*Everything is recycled in India,
Even dreams
Shashi Tharoor*

Infective endocarditis (IE) has always been challenging for the medical field, which has responded with newer innovations and persistent efforts. Habib et al. stated "Infective endocarditis is still a life-threatening disease with the frequent lethal outcome despite profound changes in its clinical, microbiological, imaging, and therapeutic profiles"¹.

Various factors affect the different aspects of IE diagnosis and management. As a developing country, India has a very polar healthcare delivery system. Primary health centers range from basic facilities that provide very primary level healthcare in rural areas to center of excellence hospitals that offer the latest medical innovations in metropolitan areas. The crucial point is the time it takes for a patient to reach to suitable center to receive the appropriate interventions. In particular, the diagnosis of IE by primary healthcare physicians must be obtained as soon as possible. Socio-economic factors play a pivotal role in patient outcomes. All three of these issues pose great challenges, especially in very large countries like India. Sengupta et al. concluded that socio-economic factors influence the clinical profile of patients presenting with IE worldwide², leading to delayed diagnosis and lower use of surgery². Gupta et al. reported observations about IE such as increasing patient age and increased proportions of patients without a history of cardiac ailments, better cultural positivity rates, an increasing incidence of staphylococcal infections, increased usage of transesophageal echocardiography (TEE), and increasing elective surgery rates³.

Gupta et al. summarized the risk factors for IE as a longer lifespan contributing to degenerative heart disease and the risk of immune suppression due to diabetes, human immunodeficiency virus, immunosuppressive drugs, and intravenous drug abuse⁴.

Various procedures require invasive instruments for the gastrointestinal and genitourinary tracts, arteriovenous fistula for dialysis, pacemaker and defibrillator implantation, and immunosuppressive therapy⁴. Few cases (10–15%) reportedly required healthcare intervention⁵ than IE due to rheumatic heart disease⁴.

Fever, heart murmur, and splenomegaly should be considered highly suggestive of IE and lead to its early diagnosis⁴.

The clinical presentation can vary but most often includes the following (in order of most common to least common): fever, chills or sweating, shortness of breath with a history of loss of appetite or weight, chest pain, and peripheral edema⁶.

The microbiological profile involves a wide spectrum of species including staphylococci, streptococci, enterococci, *Streptococcus gallolyticus*, *Streptococci viridians*, *Streptococcus sanguis*, *Streptococcus bovis*, *Streptococcus mutans*, *Streptococcus mitis*, and others such as *Coxiellaburnetii*, *Legionella* spp., *Chlamydia*, *Mycoplasma* spp., *Streptobacillus moniliformis*, *Salmonella* spp., *Brucella* spp., *Bartonella* spp., *Tropheryma whipplei*, *Pseudomonas aeruginosa*, and the HACEK group (*Haemophilus*, *Aggregatibacter*, *Cardiobacterium*, *Eikenella*, and *Kingella*)^{1,4}.

After an 11-year study, Navneet et al. concluded that predominant sites affected by IE include the tricuspid valve, followed by the mitral valve and the aortic and pulmonary valves⁶. Multivalvular involvement is also encountered. Vegetations are commonly 10–30 mm in diameter⁶. Blood cultures using modified Duke's criteria and two-dimensional echocardiography/TEE/transthoracic echocardiography (TTE) remain the principal diagnostic modalities. However, culture positivity rates vary widely nationwide (30–70%)^{7,8}. Different non-invasive techniques such as multi-slice computed tomography, magnetic resonance imaging, and nuclear imaging such as ¹⁸F-fluorodeoxyglucose positron emission tomography are gaining popularity¹. Echocardiography can be useful for predicting complications based on vegetation size, mobility, extent, and consistency⁴. TTE is the procedure of choice⁹. TEE is better in cases of prosthetic valves since its image quality is superior due to higher transducer frequency and no interference of lung tissue⁹. Abscesses, vegetations, and destructive lesions are the anatomical features and main findings of IE on echocardiography¹⁰. Polymerase chain reaction (PCR) amplification of prokaryotic 16S rDNA (recombinant deoxyribonucleic acid) is helpful for demonstrating the presence of bacteria within the heart valve⁴. Newer PCR techniques include nested PCR, real-time PCR, and LightCycler technology¹¹, but the above techniques are not readily available or cost-effective in developing countries.

Medical management consists of various regimens including injectable vancomycin, gentamycin, ceftriaxone, nafcillin, oxacillin, cefazolin, and rifampin, which are used according to the organism isolated in culture. An increasing trend in surgical intervention is aiming to lower mortality rates. Shock, congestive heart failure, and staphylococcal endocarditis are associated with a higher mortality risk in India⁷ as well as other parts of the world^{8,12}. The disease profile of patients is shifting from young patients with rheumatic heart disease to those with prosthetic valves or underlying valvular disease⁷.

Artigo recebido em 5/3/2022; revisado em 5/15/2022; aceito em 5/25/2022

DOI: 10.47593/2675-312X/20223502eed_15

Surgical management and timing are crucial in IE. Indications for surgery are heart failure, uncontrolled infection, and embolism risk¹³. Two major societies, the European Society of Cardiology (ESC) and the American Heart Association (AHA)/American College of Cardiology (ACC), agree on these indications but differ in some areas. The ESC proposes urgent/emergent versus elective surgery, whereas the ACC/AHA recommends early surgery before antibiotics are stopped¹³. Surgery is recommended by the ACC/AHA for vegetations >10 mm versus by the ESC for those >30 mm¹³.

The biggest challenge in the Indian subcontinent is obtaining sterile blood cultures since tested patients have likely already received antibiotics from their primary care physicians. Around 2.5–31% of cases in India are blood culture–negative IE due to the

use of antibiotics before diagnosis and poor adherence to blood culture guidelines⁴. Strong suspicion, correlation between clinical findings and the history and work-up leads to early detection and better outcomes. Thus, the need for microbiology labs and echocardiography facilities across India for early detection is crucial. The second hurdle is a reluctance to receive surgical intervention; however, in-depth counseling can remedy this barrier. This response has ramped up in India over the past few decades. Early suspicion leads to early detection is seen, and increases in medical and surgical interventions are helping fight IE.

My Approach to Imaging the Atrial Septal Defect by Three-Dimensional Echocardiography

Como Eu Faço a Avaliação Ecocardiográfica Tridimensional da Comunicação Interatrial

Dante Pazzanese Institute of Cardiology¹, São Paulo, SP, Brazil; Heart Institute of Hospital das Clínicas, School of Medicine, University of São Paulo (InCor-HCFMUSP)², São Paulo, SP, Brazil.

Daniela Lago Kreuzig^{1,2}

Atrial septal defects (ASDs) correspond to 6–10% of all congenital heart diseases and are more prevalent in women; moreover, an estimated 60–75% of all cases correspond to ostium secundum (OS) ASDs, a defect affecting the intermediate septal region¹.

Transthoracic echocardiography (TTE) can be used to identify the defect, quantify the hemodynamic repercussions, estimate the pulmonary pressure, and identify other associated anomalies. Transesophageal echocardiography (TEE) is indicated for greater anatomical definitions, mainly in adults or in children with large defects in whom it is necessary to assess eligibility for percutaneous treatment.

Percutaneous treatment using a prosthesis is indicated in the following ASD cases: 1) OS type; 2) diameter less than 35 mm; 3) normal pulmonary venous drainage; 4) favorable borders around the defect (greater than 5 mm) except for the anterosuperior border, which may be absent; 5) hemodynamic repercussions (pulmonary and systemic flow ratio Qp/Qs > 1.5); 6) absence of fixed pulmonary hypertension; and 7) no other anomaly indicated for surgical treatment^{1,2}.

Three-dimensional (3D) echocardiography has become significantly relevant in this context of percutaneous treatment, since more than 90% of OS ASD cases are eligible for intervention. This technology is used in the echocardiography laboratory, mainly through transesophageal

complementation in adults and patients weighting over 30 kg³. In our clinical practice, with the advent of more modern, smaller-caliber probes, we can perform this test in patients weighing more than 20 kg despite it not being recommended by the manufacturer.

However, the great advantage of the 3D technique is its use in the hemodynamics laboratory to guide closure of the OS ASD, which has a complex anatomy.

In my view, 3D acquisition in the pediatric population via the transthoracic window is very valuable for analyzing valves, performing volumetric assessments, and identifying particularities of complex heart diseases during surgical planning despite the limitations related to a high heart rate and breathing and movement artifacts. However, the specific anatomical detailing of the interatrial septum is usually insufficient and TEE resolution is superior considering its posterior location. Therefore, when treating a child with a large OS ASD, a candidate for percutaneous closure, I prefer to complement it with TEE, always under anesthesia, which results in a better quality test with fewer artifacts. Also, if the patient's weight allows it, we pass a 3D probe. Another issue of paramount importance is optimization of the two-dimensional (2D) image before 3D acquisition, which requires use of electrocardiography.

Next I will describe OS ASD assessment using the 3D technology aimed at percutaneous closure, i.e., via TTE and consider the different modes of acquisition, their advantages, and their use for this purpose.

Pre-procedural assessment

At the end of a detailed 2D TEE with a full septal analysis from the four-chamber view to bicaval section and color mapping, we commence the 3D image acquisition. The en-face projection of the ASD and the defect's positioning in the anatomic position provide valuable information from a single image: size, shape, location in the interatrial septum, characteristics of the defect's borders, and the presence of additional fenestration³.

I usually start the 3D evaluation from the perspective of the right atrium to facilitate the identification of anatomical markers². I acquire a medium angle block (3D or 4D zoom) or a large block (full-volume using the two-section tool) starting from an initial bicaval section and proceeding with approximate 90° rotation in the z-plane so that the superior and inferior vena cava are aligned in the vertical plane (i.e., superior vena cava at the 11 o'clock position) and the aorta in the anterior and superior region. I prefer not to use the narrow-angle mode for acquisition (live 3D or bird's eye

My Approach To

view) or very high magnification due to a loss of anatomical references adjacent to the defect, which can interfere with this fundamental initial analysis⁴. From this reconstruction (Figure 1A), I can characterize the defect as unique, the OS type, having an oval shape, being central, being medium-sized, and having adequate borders. Video 1 shows the same ASD and allows assessment of the occurrence of dynamic variation in its dimension with the cardiac cycle.

We obtain the view of the left atrium² after 180° rotation on the axis of the AD panorama in an anatomical position (like turning the pages of a book) (Figure 1B, Video 2). The right superior pulmonary vein is adjacent to the superior vena cava (i.e., right superior pulmonary vein at the 1 o'clock position), the aorta is in a superior but leftward position, and the mitral valve is inferiorly and anteriorly located.

The ASD borders are classified to improve communication between the operator and the hemodynamics professional as follows: anteroinferior and superoposterior (in apical four-chamber view at 0°, border close to the atrioventricular valves and contralateral); anterosuperior and posterior (on the short axis of the aortic valve, at about 45°, border related to the aorta and contralateral); and, finally, posterosuperior and posteroinferior (in bicaval view at about 100° near the superior and inferior vena cava, respectively)^{5,6}.

Multiplanar reconstruction in three axes is possible after a high-quality 3D image is obtained to quantify measurements such as distance and/or area (Flexi-slice or 3DQ software). Thus, we obtain the true transverse plane of the defect (Figure 2), which allows us to make linear measurements comparable to those performed through standard 2D TEE

A, anterior; Ao, aorta; CS, coronary sinus; I, inferior; IVC, inferior vena cava; MV, mitral valve; OS ASD, ostium secundum atrial septal defect; P, posterior; RSPV, right superior pulmonary vein; S, superior; SVC, superior vena cava; and TV, tricuspid valve.

Figure 1 – A) Three-dimensional image acquired by large block mode (full-volume) and manipulated by the two-sections tool starting from the bicaval section of the interatrial septum on transesophageal echocardiography. An en-face OS ASD is visible on the right atrial view in the anatomical position with adequate borders that is eligible for percutaneous closure. **B)** The same image taken from the left atrial perspective.

Ao, aorta; LA, left atrium; OS ASD, ostium secundum atrial septal defect; RA, right atrium.

Figure 2 – Multiplanar reconstruction performed in three axes (flexi-slice) from a three-dimensional transesophageal echocardiography image taken in the true transverse plane of an OS ASD to measure the defect in its largest and smallest diameters (bottom right).

sections². Measuring the largest and smallest diameter of an ASD during atrial diastole is routinely performed. Handling the 3D image substantially improves the 2D understanding of septal defects with time and experience. Figure 3 compares the 3D image of two OS ASDs with their respective 2D sections and borders.

The most inferior and posterior region of the interatrial septum is the most difficult to access since it is closer to the transesophageal probe. However, most OS ASDs are located in the anterosuperior portion of the septum. It is mandatory to search for additional small defects in the presence of a larger anterosuperior OS ASD and a thin and redundant posterior or posteroinferior septum (even aneurysmal), which is present in an estimated 2.7% of cases⁷.

Using this technology associated with color mapping (3D color view) to assess a simple OS ASD does not usually add information in the pre-assessment but substantially reduces the image frame rate. On the other hand, the tool with simultaneous 2D sections with color mapping (multidimensional or X-plane), which can be orthogonal in the presence of septa with several fenestrations, can help define the number, location, and proximity of fenestrations to one another.

Finally, the 3D assessment of an ASD is not time-consuming and image handling is concomitant with the test and performed by the device.

Intra-procedural assessment

The use of TEE to guide the percutaneous ASD closure requires knowledge of interatrial septal anatomy and the procedure's steps. The echocardiographer must help cross the defect with the catheter, position the guides and catheters in the pulmonary veins (usually in the left superior pulmonary vein), measure the defect in several planes, measure the diameter with a balloon catheter (as described later), open the left disk, waist, and right disk, position the device, and analyze the final result⁵. Videos 3, 4 and, 5 show 3D images of these steps. The imaging professional should inform the decision of which prosthesis is the best for the particular case.

A balloon catheter is usually passed through the ASD and slowly and progressively inflated during the echocardiographic evaluation with color mapping process. The outer to outer border of the balloon is measured at the moment the transeptal flow ceases (stop-flow technique)². The chosen device is usually up to 2 mm above this measurement. Small fenestrations are commonly found in a thin redundant region of the septum (usually posteroinferiorly) after balloon inflation at the largest ASD. However, some hemodynamic professionals skip this step in the presence of a single OS ASD with thick and firm borders and opt for an overestimated prosthesis with a waist 20–30% larger than the baseline ASD measurement obtained by standard TEE sections⁸.

The 3D complementation has great value in complex ASD cases such as an aneurysmal interatrial septum with multiple

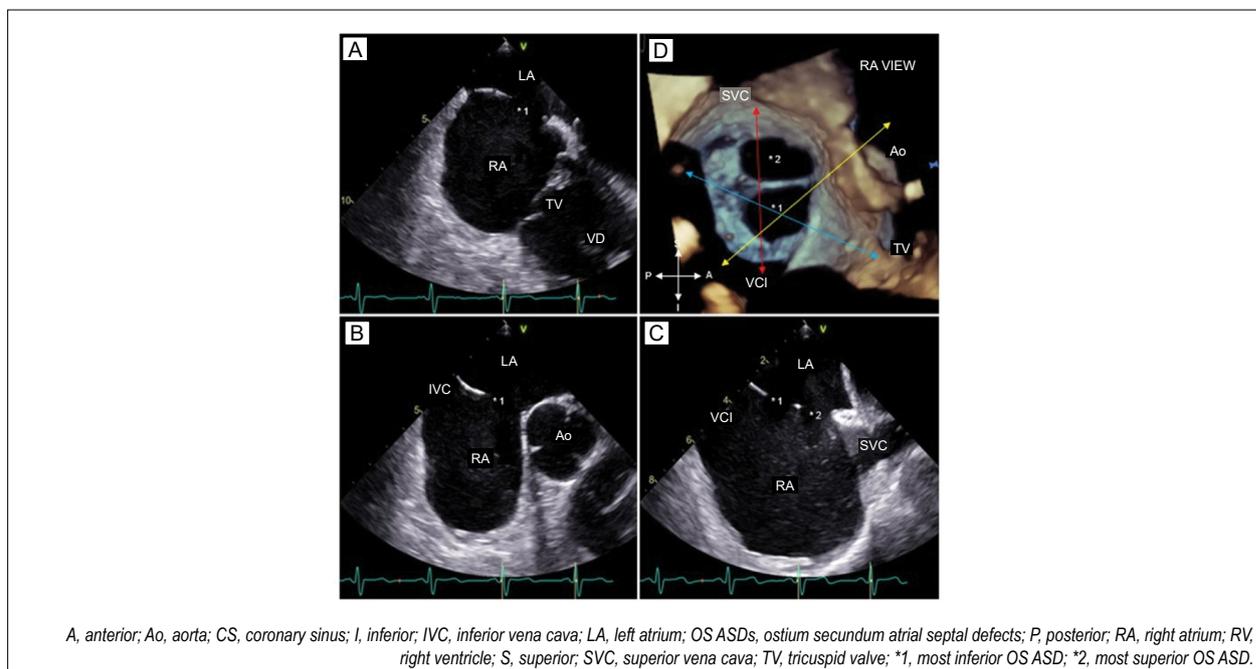

Figure 3 – Complex case of two OS ASDs assessed by two- and three-dimensional transesophageal echocardiography in the hemodynamics laboratory. A) Apical four-chamber view at 0° demonstrating the lowest ASD with adequate anteroinferior and superoposterior borders. Note that the border related to the atrioventricular valves is thicker and firmer. B) Short-axis view of the aortic valve at approximately 45° demonstrating only one of the ASDs with a deficient anterosuperior border. In this example, note that the inferior vena cava outflow is also considered in the section. C) The bicaval section at approximately 100°, with visualization of the two ASDs in two-dimensional view and posterosuperior and posteroinferior borders of appropriate dimensions. D) Three-dimensional view of the interatrial septum from the perspective of the right atrium showing the two large oval similarly sized ASDs, one superior to the other. Clearer anatomical definition was obtained by three-dimensional technology in this case. The colored arrows represent the corresponding two-dimensional sections: blue (A), yellow (B), and red (C).

My Approach To

holes, two orifices distant from one another, the absence of one or more borders, and very large holes (>28 mm).

An aneurysmal interatrial septum must be very carefully analyzed and previous gain adjustments made to avoid misinterpretation of a drop-out image (due to a thin and mobile septum) as an additional ASD after 3D acquisition.

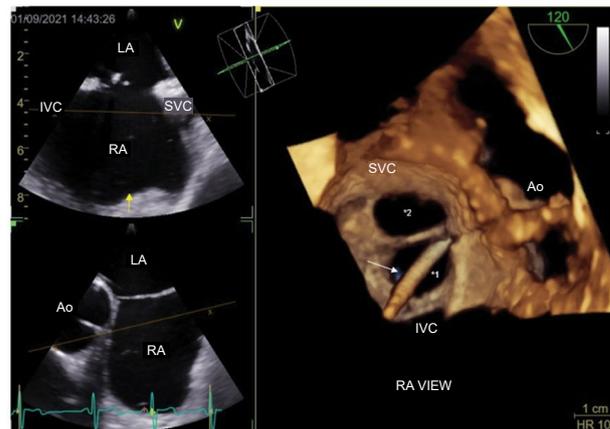

It is difficult to locate the hole through which guides or catheters can be passed in 2D tests in the presence of two or more holes, for example, considering that they may be superimposed. In this context, we can use two tricks of 3D technology. First, we can use two simultaneous 2D sections (multidimensional or X-plane) to distinguish the two holes with the advantage of the greater temporal and spatial resolution. Second, we can use the real-time image of a thin 3D slice with direct visualization of the material used by the hemodynamics

professional passing through a certain hole. Figure 4 and Video 6 exemplify this procedure.

Another advantage of assessing the entire interatrial septum in the scenario of multiple defects is the decision to use a device for a septum with several fenestrations, a thin waist, or, in the case of defects that are quite distant from each other, the choice of two prostheses for the same patient. Figure 5 and Video 7 show the final result after the implantation of two prostheses in the same patient to close two large defects.

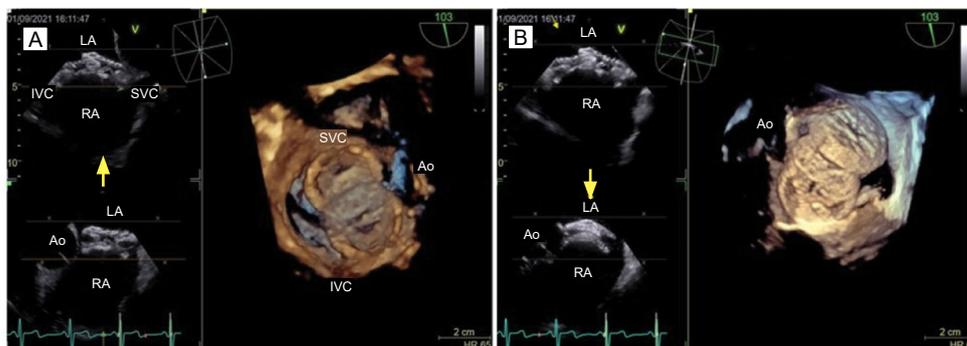

The conventional 2D technique associated with color mapping satisfactorily ensures prosthesis positioning, identifies borders between disks, and assesses heart valve and pericardial effusions at the end of the procedure.

ASDs with a more anterior and superior location in the absence of the aortic borders are more often associated with

Ao, aorta; IVC: inferior vena cava, LA, left atrium; OS ASDs, ostium secundum atrial septal defects; RA, right atrium; RA VIEW, view of the right atrium; SVC, superior vena cava; *1, most inferior OS ASD; *2, most superior OS ASD.

Figure 4 – Three-dimensional view of the interatrial septum from the right atrium showing two large OS ASDs and the catheter (arrow) passing through the most inferior ASD. Note the best anatomical detailing by three-dimensional transesophageal echocardiography technology to guide the interventional procedure of this complex case.

RA: right atrium; LA: left atrium; Ao: aorta; IVC: inferior vena cava; OS ASDs, ostium secundum atrial septal defects; SVC: superior vena cava.

Figure 5 – A) Three-dimensional image of the interatrial septum with a right atrial view demonstrating the final result after the occlusion of both OS ASDs with two prostheses, in an anatomical position. B) Same image from left atrium perspective.

aortic or atrial roof erosion. The 3D analysis of this region, including the transverse sinus, enables close follow-up due to the greater risk in such cases².

Device embolization is a rare (0.1–0.4%) but potentially serious event^{1,2} that usually occurs early and requires re-catheterization or even surgery. The main cause of embolization is an undersized defect, especially in cases with redundant septa and the absence of one or more borders. Before releasing the device, any major and unusual movement can cause prosthesis instability and increase the risk of embolization.

The 3D assessments with color mapping are used in selected cases. In the presence of residual communication after closing the defect with a prosthesis, this technology defines flow size, shape, and proximity to the disk and estimates possible spontaneous closure during patient follow-up². Another clinical condition is right or left ventricular diastolic dysfunction in which it is necessary to create a hole through the prosthesis to serve as a drain right after defect closure. In cases of congenital heart diseases such as pulmonary atresia with intact interventricular septum associated with OS ASD with reperfusion, these holes allow some flow to be directed from the right to left atrium in the presence of diastolic right ventricular dysfunction, thus avoiding right heart failure due to unsaturation. On the other hand, in an older population already presenting with left ventricular diastolic dysfunction, the outflow would be from the left to right atrium to avoid abrupt volume overload in the left atrium and the potential for acute pulmonary edema. Figure 6 shows the case of an older patient with grade II diastolic dysfunction that persisted after an ASD occlusion test with a balloon catheter for ten minutes, during which it was decided to mechanically create two holes through the prosthesis mesh. These holes may close spontaneously during the normal prosthesis epithelialization process, but this benefit would be expected for a short time after the procedure.

Post-procedure assessment

TTE should be performed 24 hours after the procedure to assess device positioning and identify any pericardial effusions. It should then be repeated after 1, 3, 6, and 12 months and annually thereafter¹. Transesophageal complementation is not necessary in cases of a normal progression and satisfactory acoustic window. The right heart chambers are significantly reduced and greater filling occurs of the left chambers, with cardiac remodeling evident at 3 months after the procedure. Small residual periprosthetic flows may disappear during the prosthesis epithelialization process that occurs during the first 6 months after catheterization. Acetylsalicylic acid anti-aggregation (3–5 mg/kg/day; maximum dose, 100 mg/day) is necessary during this period⁸. However, small residual flow persists in 3% of cases at 1 year after prosthesis implantation². The prophylaxis for bacterial endocarditis should be extended if residual flow persists⁸.

TEE is indicated in selected cases, such as in the presence of residual or additional ASD with hemodynamic repercussions. In this scenario, 3D technology can be used to aggregate information for reintervention discussion purposes.

Final considerations

Percutaneous treatment is currently the treatment of choice for OS ASD with a favorable anatomy. The procedure-associated mortality rate is very low (0.05%), below that associated with surgery (0.13%)².

Echocardiography for interventional procedures is a growing and evolving area. The role of 3D echocardiography in the context of percutaneous OS ASD closure was highlighted here, especially in complex cases encountered in a hemodynamics laboratory.

Conflict of interest

The author declares a potential conflict of interest for being a consultant for Supri, Invasive, Tecmed and Boynton.

My Approach to Echocardiography in Radiofrequency Ablation of Hypertrophic Obstructive Cardiomyopathy

Como Eu Faço Ecocardiograma na Ablação por Radiofrequência da Cardiomiopatia Hipertrófica Obstrutiva

Antonio Tito Paladino, Andrea de Andrade Vilela, Jorge Eduardo Assef, Bruno Pereira Valdigem

Introduction

Hypertrophic cardiomyopathy (HCM), an autosomal dominant genetic disease that affects one in 500 people,¹ is considered the most common isolated form of hereditary heart disease. HCM is characterized by varying degrees of ventricular hypertrophy, myocardial fiber disarray, interstitial fibrosis, and microvascular disease in the absence of cardiac or systemic conditions to justify these findings.²

Echocardiography, an invaluable tool for the diagnosis and follow-up of patients with HCM, is used to assess morphology, hemodynamic disorders, left ventricular (LV) function, and patient prognosis.³ It also has a fundamental role in cases of hypertrophic obstructive cardiomyopathy (HOCM) in the indication of invasive treatments. Radiofrequency ablation (RFA) is a possible treatment under study.

After briefly reviewing HCM, we will describe the role of echocardiography in patient selection, intraprocedural RFA, and follow-up.

Genetic basis

HCM is caused by mutations in genes encoding the sarcomere protein, Z disk, or intracellular calcium modulators.⁴ More than 1,500 mutations have been identified among more than 11 genes.⁴

Pathophysiological mechanisms

The combination of left ventricular outflow tract (LVOT) obstruction (LVOTO), mitral regurgitation (MR), diastolic dysfunction, and myocardial ischemia comprise the pathophysiological basis of HCM.⁵

The distinction between non-obstructive HCM and HOCM has great clinical importance, as the two conditions have different therapeutic strategies and prognosis.⁶

HOCM has a prevalence of one in 1,500 people.

Keywords

Echocardiography; Cardiac Hypertrophy; Ablation, Radio Frequency.

Mailing Address: Antonio Tito Paladino •

E-mail: atpf40@gmail.com

Manuscript received 3/16/2022; revised 3/17/2022; accepted 3/31/2022.

DOI: 10.47593/2675-312X/20223502ecom28

About one-third of patients with HCM have the non-obstructive form, one-third have significant obstruction at rest (defined as an instantaneous peak pressure gradient ≥ 30 mmHg), and one-third have latent obstruction (peak pressure gradient ≥ 30 mmHg after provocative maneuvers).⁶ A pressure gradient ≥ 50 mmHg is considered hemodynamically important.

Obstruction is determined by an interaction between the septum, mitral valve, and subvalvular apparatus in addition to flow vectors generated in the ventricular cavity. The mechanisms responsible for LVOTO are: a) septal hypertrophy with LVOT narrowing, which increases the velocity and displaces the blood flow trajectory, which end up “dragging” the anterior mitral valve leaflets toward the interventricular septum⁷ (Figure 1, Videos 1A and B); and b) morphological changes in the mitral valve apparatus (papillary muscles and anterior leaflet implantation and/or dimension) that may contribute to LVOTO.⁸

Left midventricular obstruction occurs in approximately 10% of patients with HCM; these patients often present with heart failure symptoms and are at increased risk of sudden death (SD) (Figure 2, Videos 2A and B).¹⁰

Mitral valve systolic anterior motion (SAM) is greater on the anterior versus posterior leaflet, resulting in coaptation distortion and dynamic mid-systolic regurgitation that is often directed to the lateral and posterior wall of the left atrium. The degree of MR varies according to the degree of LVOTO and the size of the posterior leaflet.¹⁰

The presence of a central or anterior jet should raise the suspicion of a primary mitral valve anomaly; in these cases, transesophageal echocardiography (TEE) is indicated to better elucidate the mechanism.²

The origins of the diastolic dysfunction and increased left ventricular filling pressures are multifactorial.¹¹ The hypertrophy, ischemia, and replacement fibrosis present in the myocardium are factors that increase myocardial stiffness and decrease compliance. The assessment of multiple parameters is recommended to define the degree of diastolic dysfunction (Figure 3).¹²

Diagnosis

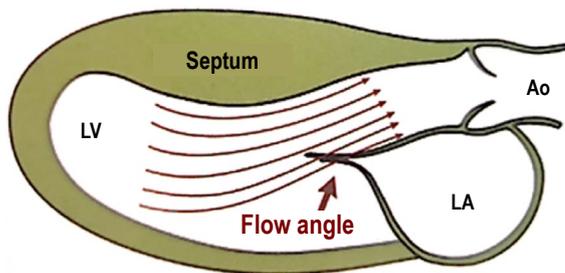

The current diagnostic criteria for HCM are:

Maximum myocardial thickness measured in diastole > 15 mm of unexplained cause (in any LV segment); and

Septal and inferolateral wall thickness ratio > 1.3 in normotensive subjects or > 1.5 in hypertensive patients.⁸

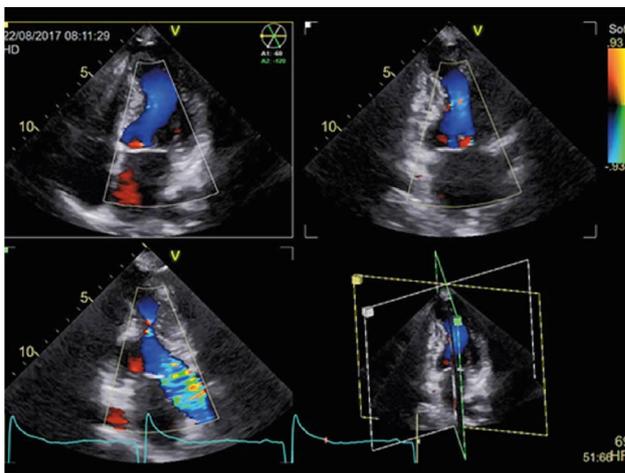

My Approach To

Figure 3 – Algorithm used to determine the degree of diastolic dysfunction and filling pressures. It can be used regardless of the presence of LVOTO.

A myocardial thickness ≥ 13 mm may be considered in the diagnosis of HCM in patients with a family history of HCM (especially if the electrocardiogram findings are abnormal). The distribution pattern of hypertrophy varies, with the asymmetric septal form being more common (70% of cases).¹³

Treatment

The pharmacological treatment of HCM is indicated in symptomatic patients. Beta-blockers are the first choice, disopyramide the second option, and verapamil is indicated for patients who are contraindicated to beta-blockers.¹⁴

In cases of significant obstruction (gradient > 50 mmHg at rest or after a provocative maneuver) with symptoms refractory to drug treatment, invasive measures may be necessary to alleviate symptoms and reduce the intraventricular gradient.¹⁵

Two invasive treatment methods are traditionally used to alleviate LVOT: surgical myectomy (SM) and alcohol septal ablation (ASA). SM is considered the gold standard and consists of partial resection of the hypertrophied septum, reducing the dynamic outflow tract obstruction.² ASA induces necrosis of the hypertrophied myocardium through the injection of alcohol into the septal perforating artery. Its use requires adequate anatomy, with the performance of contrast echocardiography being mandatory. If the contrast is not exclusively visualized in the basal septum, the procedure should be canceled.²

Recent articles on RFA reported favorable results.¹⁶ RFA is an option in situations in which there are limitations to ASA and/or in midventricular obstructions. RFA is performed by electrophysiologists in a hemodynamics room and guided by a trained echocardiographer. Anatomical (place of greater thickness) and functional (place of greater velocity) information is analyzed on echocardiography, while electroanatomical mapping provides the other necessary information.¹⁶ The patient is examined under general anesthesia in the supine position. The right femoral artery is punctured for retroaortic access to the septal region of the left ventricle, while the right femoral vein is punctured for the positioning of a quadripolar catheter in the right septum (to identify the bundle of His) and in the tip of the right ventricle. The therapeutic catheter is impacted at the point of greatest obstruction, where the radiofrequency is applied for 120 seconds (80 W and 60°C).

Role of echocardiography

In planning (preprocedural)

The purpose of the pre-RFA assessment is to determine the site of greatest myocardial thickness, assess the point of greatest flow obstruction (greater aliasing), record the maximum peak gradient, and identify changes in the mitral valve apparatus. The identification of the major primary or mixed MR makes SM more appropriate due to the possible need for mitral valve replacement. On the other hand, the identification of a significant midventricular gradient makes SM less indicated.

The morphofunctional analysis of the mitral cusps, subvalvular apparatus, and papillary muscles can elucidate the pathological mechanism mostly by TTE. TEE can be used in cases of limited acoustic window or uncertain mechanism of MR by TTE.

The LVOT flow assessment should consider the shape of the curve recorded by continuous Doppler, which typically resembles a dagger. This flow with peak mid-systolic velocity often varies with the Valsalva maneuver or physical exercise (Figures 4 and 5). Take care not to mismeasure MR as an intraventricular gradient.

During the procedure (intraprocedural)

The initial assessment is performed by TEE and aims to confirm the previously described findings: maximum peak gradient, greater aliasing point, and MR degree. Data on systolic function, left ventricular segmental contractility, and pericardial effusion are extremely important as they are compared with post-RFA findings (Figure 6).

Zero degree angles (in middle esophagus for five-chamber visualization), angles between 120° and 150° , and deep transgastric angles are the most commonly used to assess the site of greatest turbulence and measure maximum peak gradient. The gradient analysis should always consider the patient's blood pressure since, in cases of hypotension (very common during anesthesia), the value of the aorta-ventricle gradient may be higher than the one recorded in a previous examination.

The access route is usually retroaortic, but in cases in which passage of the catheter through the aortic valve is impossible (stenosis and significant calcification), access can occur via the transeptal route. The myocardium will be more echogenic (thermal injury) and slightly hypokinetic after the ablation

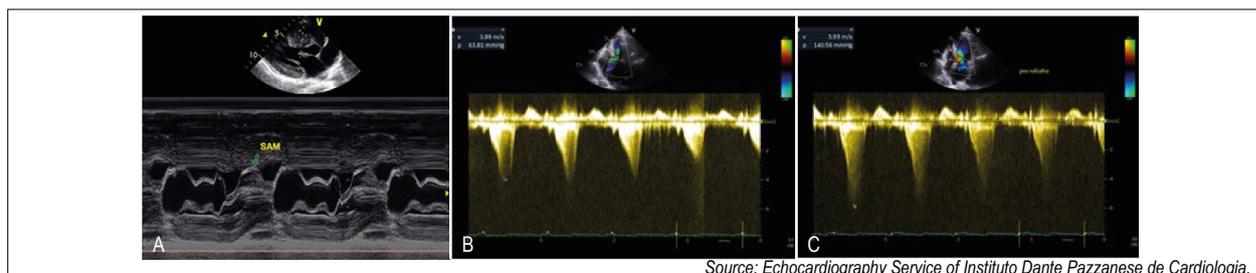

Figure 4 – Preprocedural transthoracic echocardiogram: (A) M mode showing systolic anterior motion; (B) and (C) left ventricular outflow tract flows before and after the Valsalva maneuver.

My Approach To

(Figure 7). A decreased SAM, and consequently a decreased degree of valve insufficiency, is an indicator of a good response to therapy (Figure 8, Table 1, Videos 3A and B).

In the follow-up period (postprocedural)

TTE should be performed 24–48 hours after the procedure to record the maximum peak gradient. During this period,

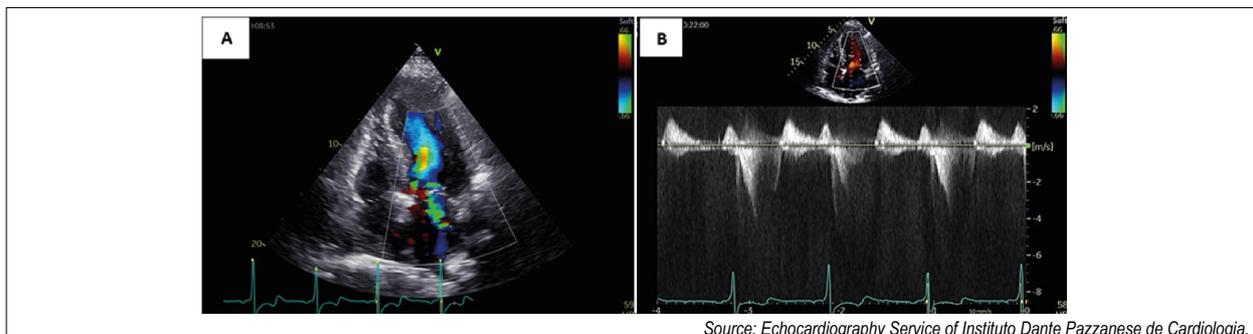

Figure 5 – Preprocedural transthoracic echocardiogram: (A) four-chamber apical view with color flow mapping showing the site of greatest systolic flow turbulence. (B) left ventricular outflow tract mid-systolic flow was also recorded in the spectral recording of mitral regurgitation.

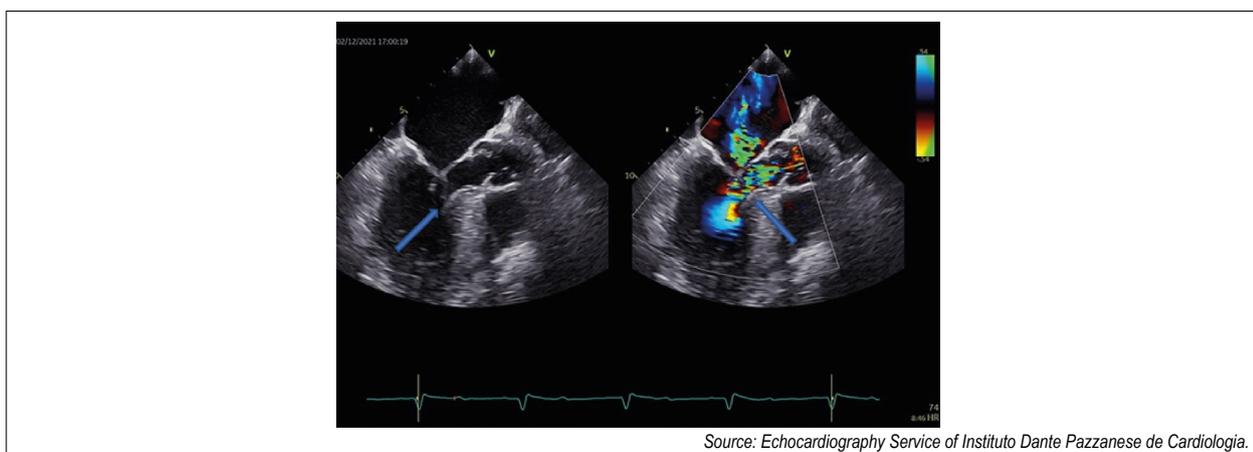

Figure 6 – Intraprocedural transesophageal echocardiography with versus without color (at 150°): mitral valve assessment and systolic anterior motion identification and location. At this angle, we could more easily identify the site of greatest flow acceleration and the degree of mitral regurgitation.

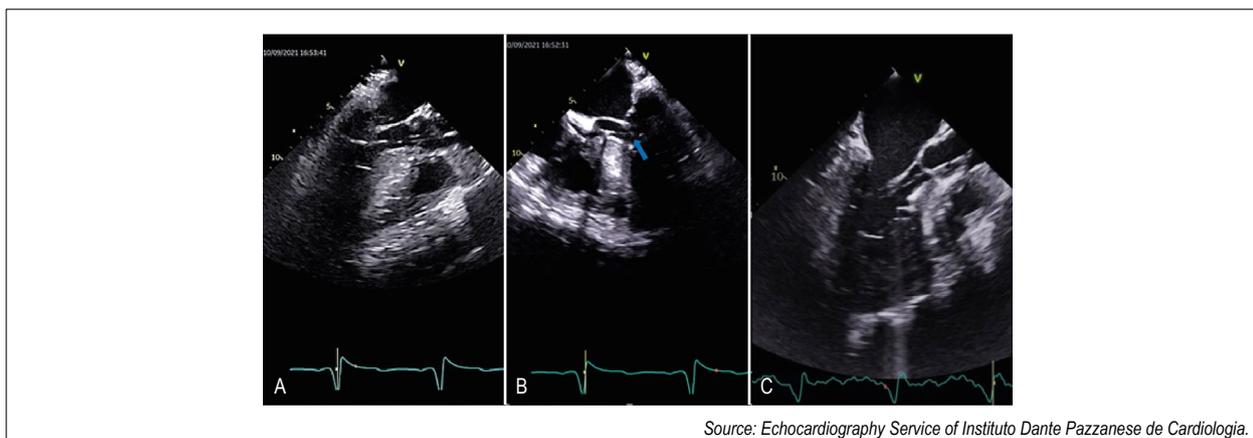

Figure 7 – Intraprocedural transesophageal echocardiography at 120° (A) and 0° (B) showing the passage of the retroaortic catheter and its repositioning in the site of greatest flow obstruction. Catheter at 120° (C) during radiofrequency application the moment the myocardium becomes more echogenic and hypokinetic due to the thermal injury.

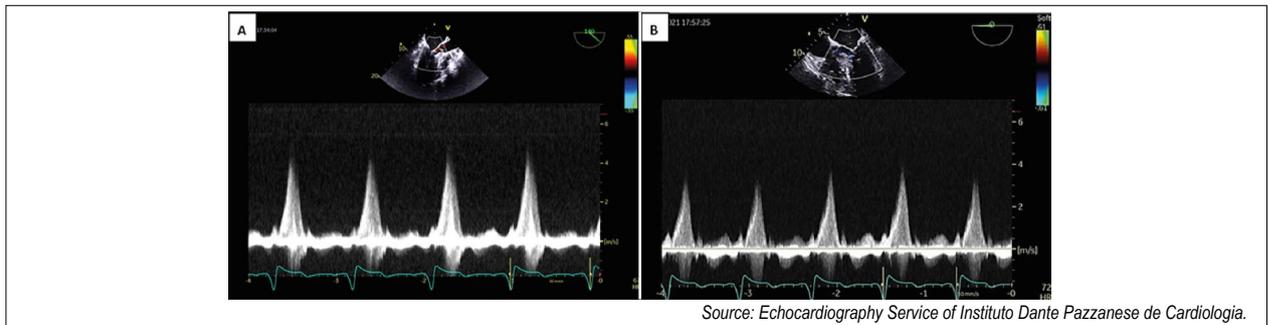

Figure 8 – Intraprocedural transesophageal echocardiography with recording of maximum left ventricular outflow tract gradients before (A) and after (B) radiofrequency ablation with estimated values of 96 mmHg and 58 mmHg, respectively.

Table 1 – Step-by-step echocardiography performed during the procedure.

Catheter access route and positioning
Step 1: Analyze gradients, valves, cavities, and pericardial space.
Step 2: Find where flow acceleration (SAM) occurs and what structures are involved.
Step 3: Guide the proper positioning of the ablation catheter (site of greatest acceleration).
During application
Step 1: Confirm that the catheter remains in the desired site.
Step 2: Confirm that the myocardium becomes hyperechoic, suggesting the therapy is effective.
Step 3: Confirm that the acceleration site changes with the application so that the catheter can be redirected, if necessary.
Step 4: Check the degree of MR, one indicator of therapeutic efficacy.
Step 5: Analyze the mitral and aortic valve apparatus to check if there was any damage during the procedure.

there are records of paradoxical gradient increase due to post-ablation wall edema.¹⁵ The use of periprocedural dexamethasone seems to reduce the edema; however, further studies are required to assess its efficacy.

Introduction

The percutaneous treatment of heart valve disease is a subject of great interest in cardiology. Percutaneous aortic valve implantation, first performed in 2002 by Alan Cribier,¹ paved the way for transcatheter treatment of the mitral valve.

The first valve-in-valve (VIV) procedures were performed to treat deteriorated bioprosthetic valves in the aortic position.^{2,3} In 2009, the group led by Dr. John Webb published the first successful case of mitral VIV.⁴ Since then, mitral VIV has been performed in numerous centers worldwide.

Mitral valve disease has a significant prevalence worldwide,⁵ particularly in Brazil. Its most frequent cause is rheumatic fever,⁶ implying more severe valve diseases at a younger age that require early and repeated surgical procedures.⁷ Knowing that bioprosthetic valve replacement is associated with high morbidity and mortality, VIV plays an extremely important role in avoiding or at least delaying surgery while improving patient quality of life.⁵

Cardiovascular imaging multimodality is essential for transcatheter mitral valve interventions.⁸ Here we will describe the role of echocardiography and computed tomography (CT) angiography in the different stages of evaluating mitral VIV.

Preprocedural assessment

Mitral VIV is a complex procedure that should only be performed after a careful heart team assessment to obtain better results.

The indication for mitral VIV depends on a series of data necessary to ensure its feasibility. Knowing the type and size of the implanted prosthesis is very useful for assessing the true internal diameter of the prosthesis and choosing the ideal endoprosthesis.⁹ In the absence of information about surgical prosthesis type, fluoroscopy can provide important data for analyses of bioprosthetic valves.¹⁰

Role of echocardiography

Complete transthoracic echocardiography (TTE) followed by preprocedural transesophageal echocardiography (TEE) is essential, and the analysis main points include:

- Identify bioprosthesis failure mechanism and its quantification, including dysfunction type, degree, and, if possible, quantification;
- Rule out factors that contraindicate mitral VIV (Table 1)¹¹;

My Approach To

- Asses anatomical factors that predict left ventricular outflow tract (LVOT) obstruction (Table 2);
- Describe the characteristics of the interatrial septum, including the fact that the presence of extensive calcification, surgical patches, thrombus, aneurysm, and exuberant lipomatous infiltration may hinder or prevent transseptal puncture;
- Analyse the hemodynamic repercussion of prosthetic dysfunction by assessing biventricular function and estimating pulmonary hypertension in which pulmonary dysfunction and hypertension worsen the outcome after surgical and/or percutaneous mitral valve treatment.^{12,13}

Role of CT angiography

CT angiography is extremely important for analyzing the residual LVOT area after percutaneous prosthesis implantation

(Figure 1) and the internal diameter of the annulus (Figure 2), which determines the implanted prosthesis size.^{14,16}

The neo-LVOT area is calculated using an appropriate software that considers the LVOT measurement, the height of the percutaneous prosthesis, and the mitral-aortic angle, with the tolerated area to enable a VIV > 170 mm².¹⁶

As for the internal diameter of the prosthesis, the correct measurement is closely associated with the type of prosthesis implanted. In prostheses with internally sutured leaflets, the true diameter (true ID) of the annulus is 1 mm smaller than the measured value; prostheses with externally sutured leaflets have an internal diameter equal to that evaluated by CT angiography.^{10,14}

Another relevant use of CT angiography is analyzing the coronary arteries, aorta, and lungs, adjuvant factors in the short- and long-term success of mitral VIV.¹⁶

Table 1 – Mitral valve-in-valve contraindications.

Absolute contraindication	Relative contraindication
Infectious endocarditis	Narrow left ventricular outflow tract
Prosthesis dehiscence	Paraprosthesis regurgitation
Extensive prosthesis thrombosis	Thrombus in the atrial cavity
Atrial septum thrombus	Major prosthesis-patient mismatch
Inferior vena cava interruption	Surgical repair of previous atrial septum
	Previous transseptal mitral valve repair

Source: Harloff et al.¹¹

Table 2 – Anatomical factors predicting LVOT obstruction.

Echocardiography	Computed tomography
Basal septal hypertrophy	Estimated neo-outflow tract < 1.7 cm ²
Small LV (<48 mm)	Less obtuse mitral-aortic angle (<115°)
Reduced distance from the IV septum to the mitral annulus (unfavorable if <17.8 mm)	

IV, interventricular; LV, left ventricle; LVOT, left ventricular outflow tract.

Intraprocedural assessment

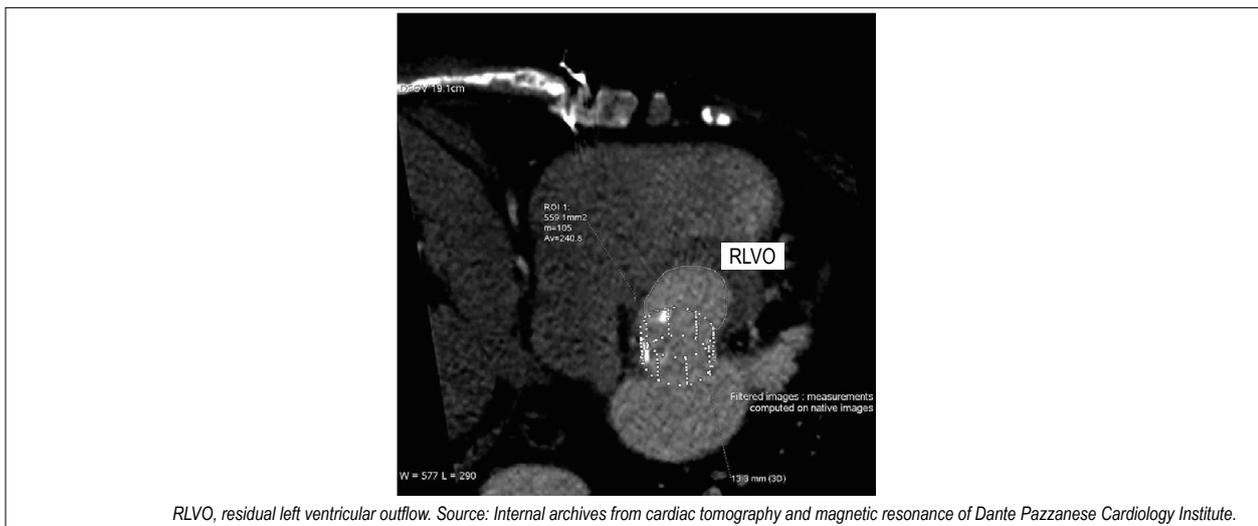

Mitral VIV should be performed in a hybrid operating room with the patient under general anesthesia (Figure 3). TEE plays a fundamental role in all the steps of the procedure as follows:

Initial assessment

TEE must be used to confirm the findings described in the preprocedural “Role of Echocardiography” assessment and rule out contraindications (Table 1).

Transseptal puncture orientation

This is a critical moment. The ideal for an appropriate puncture is the posteroinferior region of the lamina of the fossa ovalis. The use of 3D-TEE resources such as multi-D or X-plane are extremely important, as they provide optimal spatial orientation to the interventional physician, avoiding accidentally perforation of the aorta or heart cavity (Figure 4).¹⁴

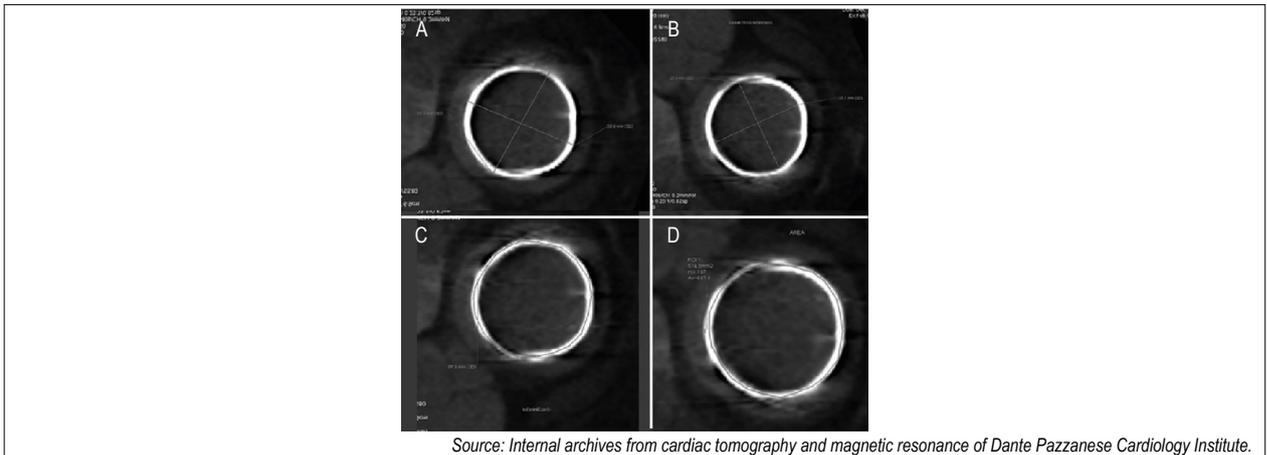

Figure 2 – Tomography. (A) Measurement of the prosthesis' annulus. (B) Measurement of the prosthesis' internal diameter. (C) Measurement of the prosthesis' perimeter. (D) Measurement of the prosthesis' area.

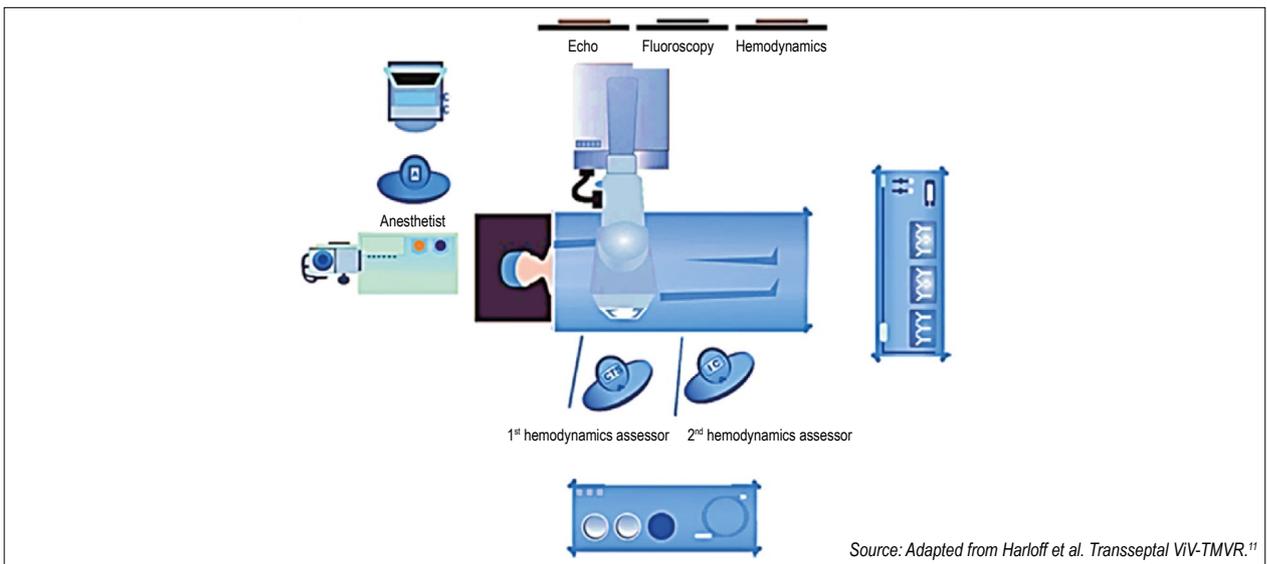

Figure 3 – hybrid operating room.

Device position

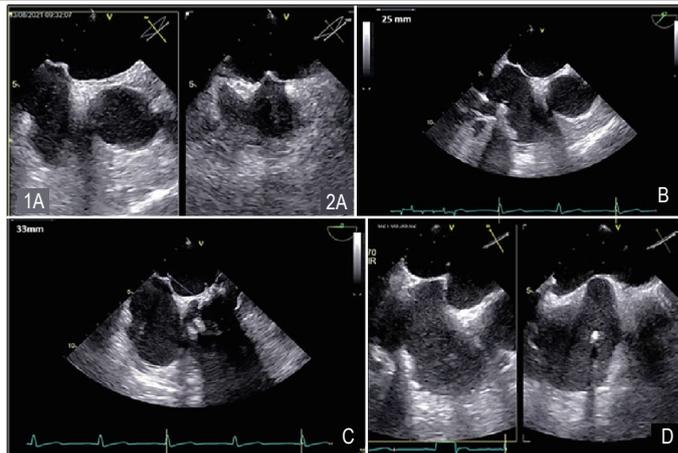

The sequence of device positioning and release is detailed in Figure 5. The height of the percutaneous prosthesis implant is calculated by neo-LVOT on CT angiography.^{14,16} The largest area usually occurs with 20% of the prosthesis in the atrial position and 80% in the ventricular position^{14,16}; and postprocedural assessment must be performed systematically to ensure the absence of complications and to confirm the proper functioning of the new prosthesis.¹⁶

- Mitral endoprosthesis assessments are performed using 2D echocardiography (ECHO), 3D ECHO, and color flow mapping. The objective is to analyze whether the endoprosthesis is adequately expanded (circular shape, mobility, and adequate opening of leaflets) and identify the flow pattern (laminar or turbulent) in addition to the presence of central and/or paraprosthetic regurgitation and

its quantification. The maximum and mean gradients of the endoprosthesis are recorded using continuous Doppler, while its area is defined using the continuity equation or 3D planimetry (figures 5 and 6 and video 1).

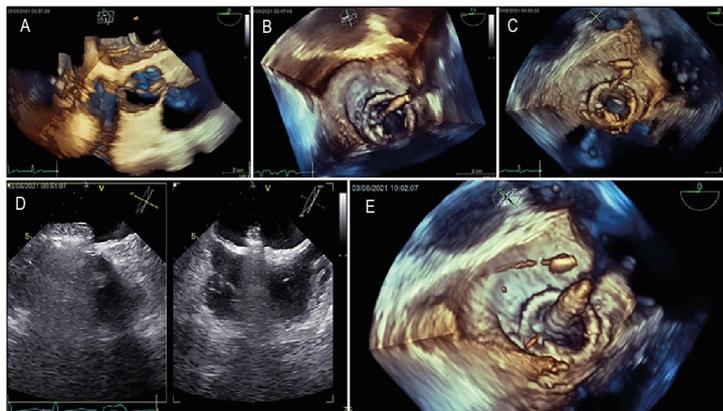

- LVOT assessment by color flow mapping and pulsed Doppler to detect high gradients. The technique of choice is deep transgastric view TEE at 0° or 5°, or even TTE (if flow alignment by TEE is inadequate). LVOT obstruction should be suspected in cases of hemodynamic deterioration immediately after endoprosthesis release and in the presence of turbulent outflow. These cases present an increase of ≥ 10 mmHg in mean LVOT gradient compared to the preprocedural assessment.¹⁷
- Ruling out the onset of pericardial effusion or changed left ventricular segmental contraction.
- Assessment of the atrial septum orifice status after puncture to determine its dimensions (orthogonal diameters and area,

My Approach To

(D) 3D planimetry used to estimate the endoprosthesis area.

preferably by 3D ECHO) and the shunt direction through the orifice.

- Assessment of right ventricular function and tricuspid regurgitation and estimation of pulmonary artery systolic pressure.

Postprocedural assessment

Numbers of published cases and follow-up times remain small and limited. Simonato et al.¹⁸ compiled a range of relevant information through a multicenter VIV and valve-in-ring registry (surgical ring endoprosthesis) in 90 different centers with 1,079 patients analyzed from 2006 to 2020, which can help the proper determination of long-term follow-up.¹⁸ The results of this study are of great interest in the field of interventional cardiology and will be briefly summarized in this document. The long-term follow-up currently used at the Dante Pazzanese Cardiology Institute (*Instituto Dante Pazzanese de Cardiologia* - IDPC) is described in Table 3.

Key VIV registry findings:¹⁸

- Prosthesis stenosis was the most frequent failure in procedure success, occurring in 8.2% of VIV cases.
- The mean gradient of the analyzed prostheses was 5.7 mmHg; 61% of the patients had mean gradients above 5 mmHg, mainly when smaller devices were used or in patients with a larger body surface area. Considering that the Mitral Valve Academic Research Consortium (mitral-VARC)¹⁶ definition of stenosis is a mean gradient above 5 mmHg.
- The implications of these findings relate to suboptimal hemodynamic performance in mitral VIV prostheses, with a higher frequency of prosthesis–patient mismatch reported in 24.5% of cases and possible shorter durability.

Table 3 – Suggested IDPC valve-in-valve follow-up.

Follow-up steps
1. Register prosthesis type and size in the first follow-up report.
2. Pre-discharge: TTE with anatomical description, mean and maximum gradients, and effective orifice area.
3. Repeat follow-up at 3, 6, and 12 months with TTE and TEE.
4. What to evaluate on TTE: anatomy, maximum and mean gradients, and area by continuity equation.
5. What to evaluate on TEE: anatomy and presence of thrombi on the ventricular or atrial face of the valve, size and flow pattern in the ASD (normal being left to right).
6. Warning signs:
↑ Man gradient > 5 mmHg
↓ Effective orifice comparison
↑ PASP
ASD shunt changed direction (right to left)

Introduction

The echocardiogram plays a central role in assessments of patients with heart failure (HF), contributing to its classification, etiology definition, severity stratification, hemodynamic assessment, and clinical follow-up.¹ HF has been historically divided according to the echocardiographic parameter left ventricular ejection fraction (LVEF). The most recent classification divided it into preserved ($\geq 50\%$), reduced ($\leq 40\%$), and slightly reduced LVEF (41–49%).^{1,2} Different societies have recently proposed a universal definition of HF that involves the presence of symptoms and signs caused by structural and/or functional cardiac changes associated with increased natriuretic peptide levels or objective evidence of congestion. The authors also highlight the importance of classifying HF according to LVEF.² (Figure 1) This article will describe the main parameters which the

clinical cardiologist should pay attention on the echocardiogram of patients with HF with reduced ejection fraction (HFrEF) and how best to use them in clinical practice.

Etiological assessment

The echocardiogram may be the first method used to define the etiology of HFrEF (Figure 2). Segmental contractility changes suggest ischemic etiology, especially if associated with inactive electrical areas on the electrocardiogram. However, they can also occur in other heart diseases. Severe valvular dysfunction associated with morphological changes suggests a valvular etiology. The presence of a digitiform apical aneurysm, inferior or inferolateral contractility changes, and right ventricular dysfunction are frequent in Chagas heart disease. Echocardiographic parameters can also be useful to define the etiology of restrictive cardiomyopathies, which may present with decreased LVEF in advanced stages. Right and left ventricular wall thickening and a myocardium with a granular aspect and preserved apical contractility are suggestive of amyloidosis. The presence of posterior and/or septal wall thickening with mitral regurgitation and a left ventricular outflow tract obstruction suggest hypertrophic cardiomyopathy, especially when the degree of hypertrophy is not explained by arterial hypertension. Finally, increased lateral and apical trabeculations are suggestive of noncompaction cardiomyopathy.

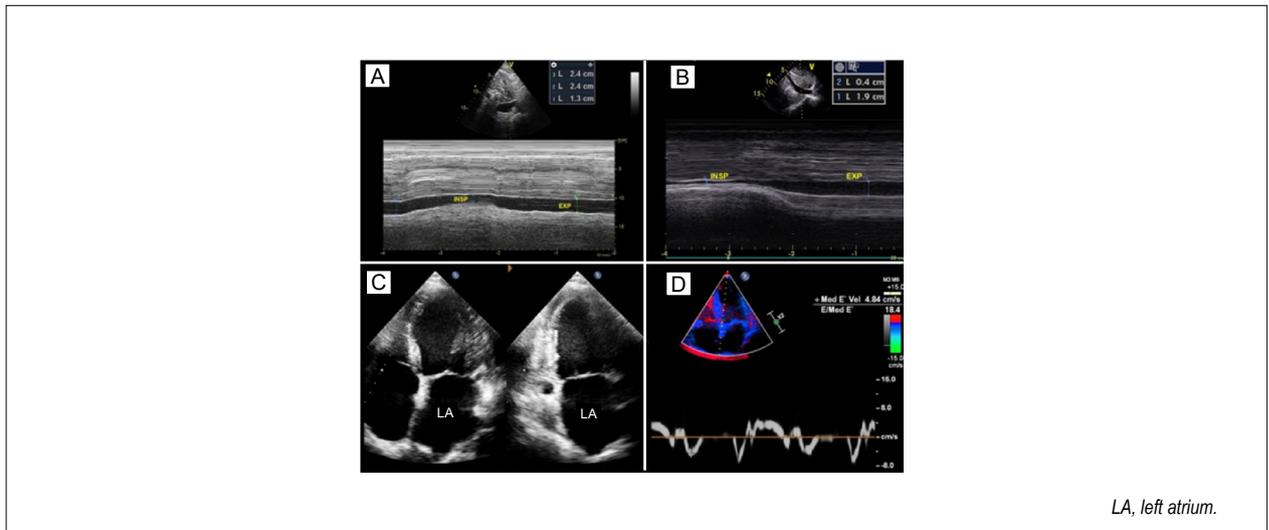

Figure 3 – Use of echocardiography to define HF etiology. A: Two-dimensional M-mode echocardiogram demonstrating an inferior vena cava measuring 2.4 cm without significant inspiratory collapse suggestive of an increased right atrial filling pressure. B: Inferior vena cava collapsing on inspiration suggestive of a low right atrial filling pressure. C: Apical four- and two-chamber windows demonstrating left atrial dilation. D: Tissue Doppler demonstrating an increased E/e' ratio suggestive of an increased left atrial filling pressure.

HFrEF (Figure 3). Right atrial pressure (RAP) can be estimated noninvasively by assessment of the diameter and respiratory variation of the inferior vena cava.¹¹ A diameter < 2.1 cm with a respiratory variation > 50% correlates with a RAP of 0–5 mmHg, while a diameter > 2.1 cm with a variation < 50% correlates with a RAP of 10–20 mmHg.¹¹ The absence of hepatic vein inspiratory collapse, right atrial dilation with left interatrial septum deviation, and tricuspid valve E/e' ratio > 6 are adjuvant parameters also correlated with a higher RAP.¹¹ These data may indicate systemic congestion in clinical practice and thus help with its clinical management.

Increased left-atrial filling pressures suggest pulmonary edema and can be noninvasively estimated by echocardiography. A study of intensive care unit patients correlated a mitral valve E/e' ratio > 15 with a pulmonary capillary pressure (PCP) > 15 with 86% sensitivity and 88% specificity.¹² However, this method is less accurate in patients with valve disease or mitral calcification, left bundle branch block, or under resynchronization therapy. Anderson et al. developed an algorithm to estimate left-chamber filling pressures with better accuracy than the use of isolated variables alone.¹³ In this algorithm, a mitral valve E/A ratio \geq 2 or two changed parameters (maximum indexed left atrial volume > 34 mL/m², peak tricuspid regurgitation velocity > 2.8 m/s, E/e' > 14) have 87% accuracy for predicting a PCP > 12 mmHg¹³. In addition, cardiac output can be estimated by pulsed Doppler in the left ventricular outflow tract, which has been increasingly used at the bedside to assess and adjust cardiogenic shock therapy.¹⁴

New echocardiographic techniques

New techniques for potential use in HFrEF have recently been described. One such technique is the strain measurement or myocardial strain index. Some studies already showed that

left ventricle GLS is a better predictor of mortality than LVEF and other echocardiographic parameters.^{15,16} It can also be used for cardiotoxicity monitoring and the diagnostic evaluation of some cardiomyopathies (e.g., the standard apical-sparing pattern in amyloidosis can be easily identified through a strain echocardiogram). Three-dimensional echocardiography is also more accurate for determining cardiac chamber volumes and function, including from the right ventricle, which has limited assessment on two-dimensional echocardiography.^{17,18} It has already been used in clinical practice for cardiotoxicity monitoring and during invasive procedures such as the MitraClip®.

Conclusion and perspectives

We believe that the role of echocardiography in HFrEF extends beyond LVEF and cavity size assessments (Figure 4). It is a widely available, noninvasive method that provides a vast set of information about the clinical condition of patients with HFrEF. The knowledge and correct interpretation of different echocardiographic parameters improves the diagnosis, prognostic assessment, treatment, and clinical follow-up of these patients.

Left Atrial Function Analysis in Patients with Functional Mitral Regurgitation Associated with Dilated Cardiomyopathy

Análise da Função Atrial Esquerda em Pacientes com Insuficiência Mitral Funcional Associada à Miocardiopatia Dilatada

Abstract

Background: Functional mitral regurgitation (FMR) is associated with dilated cardiomyopathy (DC), heart failure (HF) and worsening left atrial function (LAF). Patients with DC and FMR may present left atrial dysfunction resulting from both ventricular dysfunction and valve disease, but it is unknown whether the presence of valve disease will lead to greater LAF impairment.

Objective: This study aimed to evaluate the relationship between LAF parameters and FMR degree in patients with DC.

Methods: This cross-sectional observational study included 214 patients with DC, 46 without FMR (control group) and 168 with mild, moderate or severe FMR. An LAF analysis was performed by speckle tracking echocardiography (STE) and atrial volumetric variation.

Results: LAF analyzed by STE by means of reservoir strain, conduit strain and active contraction strain was reduced in the sample, with values of 14.3%, 8.49% and 5.92%, respectively. FMR degree was significantly associated with reservoir strain (0.27 ± 0.16 versus 0.15 ± 0.09 ; $p < 0.001$) and contraction strain (19.2 ± 7.3 versus 11.2 ± 2.7 ; $p < 0.001$). FMR was also associated with a reduced LAF assessed by volumetric analysis: total atrial emptying fraction of 0.51 ± 0.13 versus 0.34 ± 0.11 and active atrial emptying fraction of 0.27 ± 0.16 versus 0.15 ± 0.09 ($p < 0.001$).

Conclusion: In a population with DC, FMR was associated with reduced LAF assessed by STE and atrial volume variation.

Resumo

Fundamento: A insuficiência mitral funcional (IMF) está associada à miocardiopatia dilatada (MD), à insuficiência cardíaca (IC) e à piora da função atrial esquerda (FAE). A FAE pode decair tanto pela disfunção ventricular quanto pela valvopatia, mas não se sabe se esta leva a um prejuízo maior da FAE.

Objetivo: Avaliar a relação entre a piora de parâmetros de FAE com o grau de IMF, em pacientes com MD.

Métodos: Trata-se de estudo observacional transversal, que incluiu 214 pacientes com MD, sendo 46 sem IMF (controle) e 168 com IMF discreta, moderada ou grave. A análise da FAE foi realizada por ecocardiografia por speckle tracking (STE) e por variação volumétrica atrial.

Resultados: A FAE, analisada por STE – por meio do strain de reservatório, conduto e contração ativa – encontrou-se reduzida na amostra, com valores respectivos de 14,3%, 8,49% e 5,92%. O grau de IMF associou-se significativamente com os valores do strain de reservatório ($0,27 \pm 0,16$ versus $0,15 \pm 0,09$; $p < 0,001$) e de contração ($19,2 \pm 7,3$ versus $11,2 \pm 2,7$; $p < 0,001$). A IMF também apresentou correlação com a redução da FAE avaliada por análise volumétrica, observada pela medida da fração de esvaziamento atrial total (FEAT): $0,51 \pm 0,13$ versus $0,34 \pm 0,11$ e da fração de esvaziamento atrial ativa (FEAA): $0,27 \pm 0,16$ versus $0,15 \pm 0,09$ com $p < 0,001$.

Conclusão: Em uma população com MD, a presença de IMF associa-se à redução da FAE de reservatório e de contração, avaliada por STE e pela variação volumétrica atrial.

Introduction

Mitral regurgitation (MR) is characterized by blood regurgitation into the left atrium (LA) during ventricular systole. Functional MR (FMR) results from valve geometry changes induced by left ventricular (LV) dilation that separates the papillary muscles, or from annulus dilation due to atrial enlargement that creates a central area of poor valve leaflet coaptation and, subsequently, reflux into the LA. The most common causes of FMR are myocardial ischemia and dilated cardiomyopathy (DCM).¹⁻³

It is difficult to estimate the epidemiology of FMR due to differences in definitions in the literature, but some studies suggest that about 40% of patients with DCM will develop FMR.⁴⁻⁶ Data on the Brazilian population show that the main etiologies of DCM are ischemic, hypertensive, and dilated idiopathic heart failure (HF), which affect 30.1%, 20.3% and 14.6% of patients, respectively.⁷

The LA is a functional cavity that works as a volume reservoir and contractile myocardium and plays a crucial role in cardiac performance.⁸ LA function (LAF) is classically divided into three phases (reservoir, conduit, and active contraction), which can be obtained through two-dimensional echocardiography by speckle tracking (STE) or atrial volume variation.⁹⁻¹¹ Good LA functioning is even more important in patients with HF since atrial output can correspond to up to 30% of cardiac output, something relevant in patients with LV dysfunction.¹⁰

Patients with DCM and FMR may have atrial dysfunction resulting from ventricular dysfunction and valvular heart disease, but whether the presence of valvular heart disease leads to greater LAF impairment it is unknown. This study aimed to evaluate the correlation between LAF worsening assessed by STE and phasic volumetric variation and the degree of FMR in patients with DCM.

Method

Population

This cross-sectional observational study enrolled patients who underwent HF treatment in a specialized tertiary hospital in 2007–2011. The inclusion criteria were sinus rhythm; left ventricular ejection fraction (LVEF) < 40%; and mild, moderate, or severe MR with functional characteristics on two-dimensional echocardiography. The exclusion criteria were history of acute myocardial infarction or unstable angina less than 90 days before the examination; acute myocarditis; history of organic (primary) valve disease or previous valve surgery; or echocardiographic image of inadequate quality. All participants signed an informed consent form, and the institution's research ethics committee approved the study. Of the 280 patients who met the inclusion criteria, 25 were excluded due to inadequate image quality or echocardiographic monitoring, leaving 255 participants for the analysis. Of them, data were available for FMR assessment for only 214: 46 had no FMR (control group), 124 had mild FMR, 29 had moderate FMR, and 15 had severe FMR.

Echocardiography

Echocardiographic images were acquired using Vivid 7 and Vivid E9 devices (GE Healthcare), and images were

analyzed by advanced techniques (STE) on an appropriate workstation using EchoPAC PC[®] software version 6.0.1 (GE Healthcare).

Echocardiography was performed with electrocardiographic monitoring following American Society of Echocardiography guidelines.^{12,13} FMR degree was assessed following the same guidelines, favoring quantitative measures such as effective regurgitant orifice (ERO; cm²) and regurgitant volume (RV; mL).^{14,15}

Images were obtained in different phases of the cardiac cycle for LA volume measurements as recommended by Abhayaratna et al.¹⁶ Three volumes were obtained in apical four- and two-chamber windows: maximum volume (at the end of ventricular systole), pre-P-wave volume (immediately before the P-wave on electrocardiography), and minimum volume (at the end of ventricular diastole). The reservoir function is represented by the total atrial emptying fraction (TAEF) and active contraction function by the active atrial emptying fraction (AAEF). TAEF is calculated as (maximum volume - minimum volume)/maximum volume. AAEF is calculated as (pre-P volume - minimum volume)/pre-P volume.

LA strain was analyzed by STE using the software originally developed for LV assessment. This evaluation was performed in apical four- and two-chamber views with six different segments analyzed in each. Each segment generated a regional atrial strain curve. The mean between these curves in both acquisitions was used to measure the reservoir function, which corresponds to the greatest positive longitudinal strain measured after the T wave by electrocardiography and the contraction function, which corresponds to the ascending P-wave strain. The conduit function corresponds to the difference between these values (Figure 1).¹⁷

Statistical analysis

Quantitative variables were subjected to the Kolmogorov-Smirnov test for a normality assessment. Normally distributed variables are presented as mean and standard deviation. Non-normally distributed variables are described as median and interquartile range (Q1–Q3). Categorical variables are presented as percentages.

The Pearson's and Spearman's methods were used to assess the correlation between the variables representing LA function, the quantitative variables for FMR grading, and LVEF.

Analysis of variance was used to assess the association between atrial emptying volumes and fractions and reservoir, conduit, and contraction atrial strain values by FMR (mild, moderate, and severe).

Values of $p < 0.05$ were defined as significant in all analyses performed using SPSS software for Windows (version 20.0; IBM) and tabulated using Microsoft Excel 2003 software.

Results

Clinical characteristics

Most patients were men (62%), with a mean age of 59 ± 13 years and New York Heart Association functional classes II

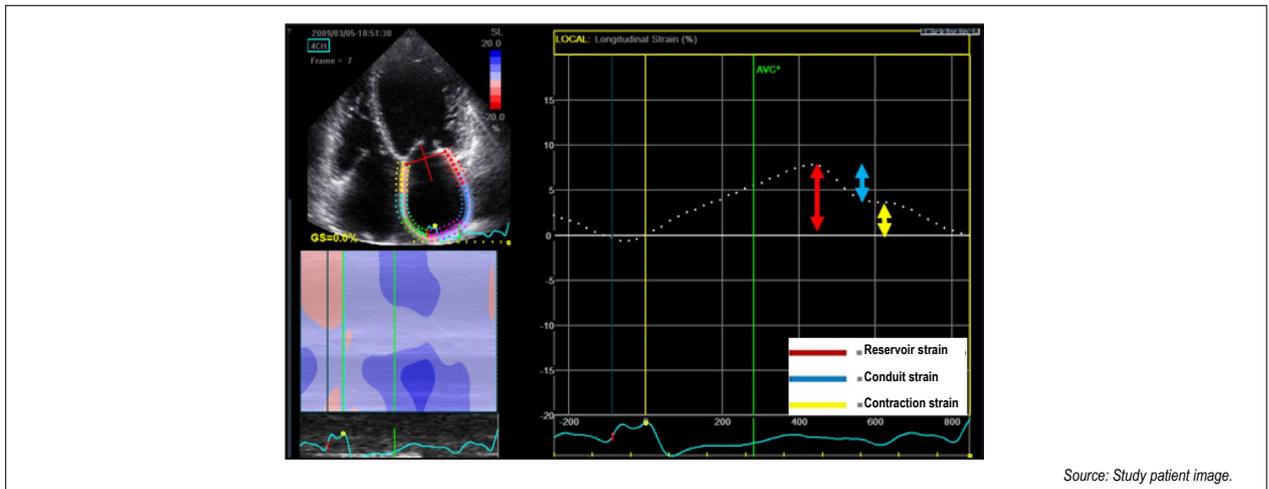

Figure 1 – Atrial strain phases by two-dimensional speckle tracking echocardiography in apical four-chamber view synchronized by QRS. The dotted curve in the center represents the mean between the regional strain curves with their reservoir and contraction strain peaks. The difference between them represents the conduit strain.

and III. The most frequent comorbidities were arterial hypertension (62.7%), coronary artery disease (32.9%), and previous infarction (38.4%).

Most patients were on optimized treatment for HF, with angiotensin-converting enzyme inhibitors being used by 65.7%, angiotensin 2 receptor blockers by 25.7%, beta-blockers by 89.8%, and spironolactone by 72%.

Table 1 demonstrates the clinical characteristics of the study population.

Echocardiographic characteristics

Most patients in the study had significant LV dysfunction, with a mean LVEF of $29.7 \pm 6.4\%$. The main echocardiographic variables are described in Table 2.

LA function

All atrial function components – reservoir, conduit and active contraction – measured by STE were significantly reduced in the sample by 14.3%, 8.49%, and 5.92%, respectively. LA volumes increased, with a mean of $45.3 \pm 17.2 \text{ mL/m}^2$ at maximum volume. The atrial function variables are described in Table 3.

The analysis of ischemic versus non-ischemic etiology showed no difference except for the maximum LA volume, which was greater in non-ischemic patients (Table 4).

Mitral regurgitation

FMR degree was significantly correlated with LAF assessed by a volume analysis using the total and active emptying fractions. The STE analysis showed that FMR degree was associated with reservoir and contraction strain. FMR degree was directly associated with increased LA volume and inversely related to LVEF. Table 5 shows the analysis of these data.

As for FMR quantitative variables, ERO and RV were directly correlated with atrial volume and inversely correlated with atrial

function. LVEF showed the same correlation pattern but with a less strong association (Table 6).

Discussion

Two findings were especially relevant in this study: variables related to LAF reservoir and contraction were reduced in this sample of patients with DCM; and FMR degree was significantly associated with most echocardiographic parameters related to volume and LAF.

Ischemic MR severity was associated with all variables related to left atrial volume, atrial emptying fractions, and reservoir and active contraction strain, possibly due to MR pathophysiology in which the blood returns to the LA, increasing its pressure and dimensions and, consequently, reducing its function. The literature reports the same finding, mostly related to organic MR as no studies on FMR are currently available. A study of 144 patients with FMR subdivided into groups 1 (absent or mild MR) and 2 (moderate or severe MR) reported a correlation between degree of regurgitation and left atrial volume, but parameters related to atrial function were not analyzed.¹⁸

As for prognosis, FMR is classically one factor associated with lower survival, worse functional class, and greater morbidity in DCM.¹⁹⁻²³ However, it is unclear whether atrial dysfunction associated with this condition represents an additional adverse prognostic factor.

LA volume has been extensively studied and is currently a more reliable LA dimension measurement than anteroposterior diameter.²⁴⁻²⁷ In fact, it has prognostic value in several cardiovascular diseases.²⁸⁻³⁷

A European multicenter study of 371 healthy participants reported indexed LA volume, TAEF, and AAEF values of 26.3 mL/m^2 , 68.5%, and 43.1%, respectively.³⁸ In our study, the atrial volumes were increased and the phasic function variables were decreased. Indexed LA volume, TAEF, and AAEF values were $45.3 \pm 17 \text{ mL/m}^2$, $42 \pm 15\%$, and $22 \pm 14\%$, respectively.

Student's t-test. LA, left atrium; SD, standard deviation.

These values tend to be lower in populations with DCM and LV systolic dysfunction. Triposkiadis *et al.* reported a correlation between AAEF reduction in idiopathic DCM and between a ischemic and control group (18 ± 10% vs. 32 ± 10% vs. 36 ± 10%, respectively; p = 0.05).³⁹ D'Andrea *et al.* reproduced this finding with an AAEF of 22.5 ± 10% for idiopathic DCM and 33.1 ± 9.3% for ischemic DCM.⁴⁰ In our study, atrial function was reduced in the entire group and no differences were observed between the ischemic and non-ischemic etiologies.

STE LAF values in patients with HF with reduced EF tend to be reduced as evaluated by Cameli *et al.*, who found values of 13 ± 11.3% for reservoir strain and of 5.26 ± 5.54% for contraction strain in a group of patients with an LVEF < 30%.⁴¹ Another study with a population with DCM and LVEF < 40% reported reservoir and contraction strain values of 12.3 ± 3.6% and 6.2 ± 1.6% in patients with increased LV filling pressures, respectively.⁴² In our sample, reservoir, contraction, and conduit functions assessed by two-dimensional strain were also decreased at 14.3%, 8.49%, and 5.92%, respectively.

Spearman correlation. LA, left atrium; LVEF, left ventricular ejection fraction; SD, standard deviation.

Table 6 - Atrial function variables, left ventricular ejection fraction, and quantitative parameters of mitral regurgitation.

Variable	MR ERO		MR RV		LVEF (Simpson's)	
	Correlation	p	Correlation	p	Correlation	p
Maximum LA volume, mL/m ²	0.516	<0.001	0.521	<0.001	-0.254	<0.001
Minimum LA volume, mL/m ²	0.502	<0.001	0.506	<0.001	-0.265	<0.001
Pre-P LA volume, mL/m ²	0.480	<0.001	0.497	<0.001	-0.285	<0.001
Total atrial emptying fraction, %	-0.373	<0.001	-0.381	<0.001	0.234	0.001
Active atrial emptying fraction, %	-0.311	<0.001	-0.289	<0.001	0.088	0.202
LA reservoir strain, %	-0.390	<0.001	-0.334	<0.001	0.344	<0.001
LA contraction strain, %	-0.451	<0.001	-0.379	<0.001	0.275	0.001
LA conduit strain, %	-0.109	0.189	-0.112	0.176	0.274	0.001

Pearson's correlation. ERO, effective regurgitant orifice; LA, left atrium; LVEF, left ventricular ejection fraction; MR, mitral regurgitation, RV, regurgitant volume.

No studies correlating these variables with the presence of FMR have been published.

The fact that we observed an association between LAF variables expressing reservoir and contraction functions and not between FMR and the conduit function may be because the latter is physiologically related to LV compliance and relaxation, which were likely to be homogeneously reduced in this DCM population regardless of FMR degree.

Further studies are needed to understand the prognostic impact of atrial dysfunction in the population with DCM and FMR, especially in terms of the genesis of atrial fibrillation, which has high morbidity and mortality rates among DCM patients.

Conclusions

Patients with myocardial ischemia and dilated cardiomyopathy (DCM) and Functional mitral regurgitation

(FMR) present global left atrium function (LAF) impairment.

FMR is associated with increased atrial volumes and reduced phasic reservoir function and atrial contraction parameters.

Left Ventricular Longitudinal Linear Displacement Versus Global Longitudinal Strain on Cardiovascular Magnetic Resonance

Deslocamento Linear Longitudinal do Ventrículo Esquerdo Comparado ao Strain Longitudinal Global por Ressonância Magnética Cardiovascular

Abstract

Background: Left ventricular (LV) systolic diastolic function is prognostic in cardiovascular diseases and can be assessed via global longitudinal strain (GLS) on echocardiography and cardiac magnetic resonance (CMR). However, GLS by CMR requires the use of expensive software. Longitudinal linear displacement (LLD) may be a simple and inexpensive alternative to GLS, but the two have not been systematically compared.

Objective: To compare LLD with GLS and LV ejection fraction (LVEF) in aortic valve disease patients and controls.

Methods: We included 44 participants (26 with aortic valve disease, 19 controls). GLS was determined using CVI42 software (Circle Cardiovascular Imaging), while the LLD linear measurements of the distance between the base/apex of the LV included maximum displacement (MD), maximum velocity in early diastole (MVED), atrioventricular junction velocity in diastasis (VDS), and VDS/MVED ratio.

Results: DM and MVED were correlated with GLS ($r=0.69$ and $r=0.65$, respectively) and LVEF ($r=0.47$ and $r=0.57$, $p<0.001$ for both). DM and MVED showed areas under the receiver operating characteristic curve (AUC) of 0.88 and 0.91, and at the best cut-off point (-0.13 and 0.66), sensitivities of 72.43% and 57.14% and specificities of 80.65% and 87.10%, respectively, compared to GLS. Using LVEF as a reference, we obtained AUC of 0.70 and 0.82, and at the best cut-off point (-0.11 and 0.61), sensitivities of 75.00% and 50.00% and specificities of 72.97% and 78.38%, respectively.

Conclusion: LLD demonstrated similar performance to that of GLS. MD derived from LLD was the best parameter during systole, while MVED was the best during diastole. Our findings demonstrate the routine, quick, and inexpensive assessment of diastolic function on CMR.

Resumo

Introdução: A função sistodiastólica do ventrículo esquerdo é prognóstica nas doenças cardiovasculares e pode ser avaliada por *strain* longitudinal global por meio de ecocardiografia e de ressonância magnética cardíaca. O *strain longitudinal global* pela ressonância magnética cardíaca exige a utilização de *software* de alto custo. O deslocamento linear longitudinal do ventrículo esquerdo pode ser uma alternativa simples e barata ao *strain* longitudinal global, porém eles não foram ainda comparados sistematicamente.

Objetivo: Comparar o deslocamento linear longitudinal com o *strain* longitudinal global e fração de ejeção do ventrículo esquerdo em valvopatias aórticas e controles.

Métodos: Incluímos 44 participantes (26 valvopatias aórticas/19 controles). O *strain* longitudinal global utilizou *software* específico (Circle Cardiovascular Imaging 42) e o deslocamento linear longitudinal apenas medidas lineares de distância entre a base e o ápex do ventrículo esquerdo, gerando deslocamento máximo, velocidade máxima no início da diástole, velocidade na diástase e a relação entre velocidade na diástase e velocidade máxima no início da diástole.

Resultados: Deslocamento máximo e velocidade máxima no início da diástole correlacionaram-se com *strain* longitudinal global ($r=0,69$ e $r=0,65$ respectivamente) e com a fração de ejeção do ventrículo esquerdo ($r=0,47$ e $r=0,57$, $p<0,001$ para ambos). Deslocamento

Manuscript received 5/11/2022; revised 5/18/2022; accepted 5/25/2022

DOI: 10.47593/2675-312X/20223502eabc304

máximo e velocidade máxima no início da diástole apresentaram área sob a curva Característica de Operação do Receptor de 0,88 e 0,91 e, no melhor ponto de corte (-0,13 e 0,66), sensibilidade de 72,43% e 57,14% e especificidade 80,65% e 87,10%, respectivamente, quando comparados ao *strain* longitudinal global. Utilizando a fração de ejeção do ventrículo esquerdo como referência, foram obtidos 0,70 e 0,82, e, no melhor ponto de corte (-0,11 e 0,61), sensibilidade de 75,00% e 50,00% e especificidade 72,97% e 78,38%, respectivamente.

Conclusão: O deslocamento linear longitudinal foi semelhante ao *strain* longitudinal global. O deslocamento máximo derivado do deslocamento linear longitudinal foi o melhor parâmetro na sístole, enquanto a velocidade máxima no início da diástole foi o melhor na diástole, o que possibilita a avaliação da função diastólica pela ressonância magnética cardíaca na rotina clínica de forma rápida e sem custo adicional.

Introduction

Systolic and diastolic dysfunction are important markers of several cardiovascular diseases in clinical practice.¹ Studies evaluating myocardial strain demonstrated high ability for the early detection of contractile dysfunction in several cardiovascular diseases.² The myocardial strain technique is based on myocardial architecture analysis and evaluates three distinct layers: subendocardial, formed by longitudinal fibers oriented from the base to the apex; middle of the wall, with circumferential fibers; and subepicardial, with longitudinal fibers oriented from the apex to the base.²

The strain is often measured by two modalities, speckle tracking by echocardiography (ECHO) and feature tracking imaging (FTI) by cardiac magnetic resonance imaging (CMRI).^{3,4} ECHO, which analyzes small groups of pixels in the myocardium created by the interaction of ultrasonic beams and the heart muscle with specific grayscale characteristics, is the most widely used modality in clinical practice. CMRI can assess GLS via two techniques. The first technique is myocardial tissue tagging, which identifies simple linear or grid patterns applied to the CMRI image during its acquisition and is considered the gold standard for assessing GLS against which ECHO was validated.⁵ However, this technique requires the acquisition of specific tagging images, demanding additional time for CMRI study.

The new FTI technique was recently developed for GLS assessments using conventional cine-MRI. This technique uses principles similar to speckle-tracking used in ECHO but that are applied to CMRI to track specific pixels characteristics throughout the cardiac cycle.⁶ Studies of patients developing diastolic dysfunction in pathologies such as aortic stenosis (AoS) and aortic insufficiency (Aoi) demonstrated a left ventricular (LV) ejection fraction (LVEF) within the normal range and changed strain, indicating the presence of a diastolic dysfunction component in addition to the incipient contractile dysfunction not detected by LVEF. These data indicate that GLS, which incorporates systolic and diastolic function, is more sensitive than LVEF for assessing ventricular contraction mechanics.^{7,8}

GLS is not usually assessed by FTI CMRI in clinical routine, as it requires additional post-processing time and specialized and expensive software. This technique requires the acquisition of endocardial and epicardial contours for all cardiac phases on a cine-MRI scan. Our group evaluated a new technique that is simple to apply, requires no specialized software, and can be performed using simple and free image viewer software. This technique is based on LV longitudinal linear displacement (LLD), more specifically on the linear basal-apical shortening of the LV. In this previous study, longitudinal shortening detected

systolic and diastolic function changes in patients with aortic valve disease (AVD) versus normal controls.

Although LLD was already compared with diastolic dysfunction by ECHO⁹ and in specific groups of patients with proven diastolic dysfunction,¹⁰ it has not yet been compared with GLS by FTI CMRI. Thus, this study aimed to compare LLD and GLS measured by the FTI technique.

Methods

Study population

This study included 26 patients with severe AVD eligible for aortic valve replacement surgery with LVEF within the normal range who underwent CMRI as part of their clinical evaluation. It also included 19 healthy controls. Of the patients with AVD, 11 (42.3%) had aortic regurgitation and 15 (57.7%) had AoS. The exclusion criteria were age below 18 and above 85 years, diabetes mellitus, systemic arterial hypertension, dyslipidemia, or significant concomitant coronary disease. All patients aged over 40 years underwent coronary angiography, and those with significant coronary artery disease (luminal stenosis > 50%) were excluded. Patients with concomitant mitral valve disease, previous cardiac surgery, or contraindications to CMRI; who were using pacemakers, metal clips, or other ferromagnetic structures; or who had claustrophobia were also excluded.

Baseline GLS and LLD were established in 19 healthy volunteers with no significant medical history. Patients underwent CMRI with a 1.5 Tesla clinical magnet (Signa CV/i; GE Medical Systems, Waukesha, WI, USA) and dedicated cardiac coil. After the heart was located, 8–12 contiguous short-axis slices covering the entire LV (8-mm slice thickness and 2-mm inter-slice interval) and long-axis slices (two- and four-chamber planes and LV outflow tract) were prescribed. Cine-MRI scans were acquired with a steady-state free precession pulse sequence with high temporal resolution (<50 ms between phases) and with other conventional parameters: TR, 3.9 ms; TE, 1.8 ms; flip angle, 45°; receiver bandwidth, ±125 kHz; field of view, 34 × 34 cm; 256 × 160 matrix; and voxel size, 1.3 × 2.1 × 8.0 mm.

Image analysis using feature tracking imaging technique to obtain GLS

Global longitudinal strain was analyzed using cine-MRI images in four-chamber long-axis view and along 20 cardiac phases. CVI42 software (Circle Cardiovascular Imaging, Calgary, Canada) and the Tissue Tracking tool were used to identify the diastolic phase, with manual definition of the endocardial and

epicardial contours, which are automatically propagated by the software to the other cardiac phases. Subsequently, myocardial GLS was automatically calculated by the software using a Eulerian mathematical principle that represents a measure of ventricular strain (Figure 1).¹¹ GLS numerical data were stored in the software and exported to data sheets for further analysis.

Image analysis using the longitudinal linear displacement (LLD) technique

As in GLS analysis, LLD was performed on cine-MRI images in four-chamber long-axis view. The basal atrioventricular junction (AVJ) position was defined in end-diastole and its longitudinal displacement was measured in relation to a reference line drawn between the LV apex (epicardium contour, low-intensity line corresponding to the myocardial and epicardial fat interface) and the lower limit (low-intensity line) of the coronary sinus running along the atrioventricular groove immediately lateral to the AVJ. A simple straight line was traced through the cardiac cycle along all phases between the basal and apical landmarks using a DICOM Webpax visualization platform (Heart Imaging Technologies, LLC, Durham, NC, USA) (Figure 2). Phase-by-phase LV longitudinal measurements were subsequently divided by the longitudinal length at end-diastole (maximum length) to provide percentage AVJ displacement values during the 20 phases.

$$(AVJ \text{ dis.}\%). \text{ AVJ dis. } (\%) = \frac{LM(\text{phase})}{CM}$$

Longitudinal displacement (D) versus time was analyzed by subtracting the maximum percentage AVJ displacement (max AVJ des. %) by the minimum for each phase (min. phase) divided by the max AVJ des. % as shown in the equation below.

$$D = \frac{AVJ \text{ dis. } (\%) \text{ Max} - \text{Min}(\text{phase})}{\text{Max AVJ dis. } (\%)}$$

LLD parameters were extracted from the generated longitudinal displacement (D) versus time graph: maximum displacement (MD), maximum velocity in early diastole (MVED), best-fit line of normalized AVJ velocity in diastasis (VDS), and VDS/MVED ratio. MD was extracted through the minimum over the data range obtained from D as shown in the equation below.

$$MD = \text{Minimum } D \text{ (phase by phase)}$$

The MVED of each participant was acquired through a regression slope on the displacement versus time graph adjusted for early diastole (Figure 2). The same method was used for VDS considering the time of diastasis.

Statistical analysis

Sample size was related to the number of patients with a confirmed diagnosis available for analysis (convenience sample), which corroborates the literature in the area.^{10,12} Normality was assessed by the Shapiro-Wilk test. Simple linear regression analyses were performed for each of the LLD parameters (MVED, VDS, MD, and VDS/MVED) with GLS and LVEF. A GLS cutoff point of -13%, which corresponds to the 99th percentile of the values measured in the control group, was used as the limit of normality. A normal LVEF was considered those greater than or equal to 55%. We evaluated the accuracy, sensitivity, and specificity of the LLD parameters (MVED, VDS, MD, and VDS/MVED) using FTI GLS and LVEF with the normality thresholds defined above as the reference method. The receiver operating characteristic (ROC) curves and the cut-point test were used to define the optimal sensitivity and specificity threshold. Stata software version 13 for Macintosh was used for the statistical analysis considering values of p < 0.05 as statistically significant.

Results

Population characteristics

The group of healthy volunteers included 10 men and nine women with a mean age of 43.1 ± 11.8 years (range, 24–58 years). The patient group included 19 men and seven women with a mean age of 46.8 ± 13.7 years (range, 26–72 years). The participants' clinical characteristics including cardiovascular history, risk factors, and CMRI data are presented in Table 1.

Cardiovascular magnetic resonance imaging

Table 2 shows the results of GLS, morphology, volume, and global LV function measurements for all groups. Figure 3 shows sample GLS analyses in each group and endocardial and epicardial contours.

The MVED, MD, VDS, and VDS/MVED correlation coefficients (r) and (p) are presented in Table 3. MD and MVED showed strong and significant correlations compared with the GLS approach for both the total sample and for only patients with AVD. Compared with LVEF, the correlations were more evident and significant for all participants (Table 3). The linear regression of MD versus GLS showed a positive correlation with an $r = 0.69$ and $p < 0.001$ for the total sample and an $r = 0.66$ and $p < 0.001$ for patients with AVD (Figure 4). Comparison of MD and LVEF resulted in an $r = 0.47$ and $p < 0.001$ (Figure 4).

The linear regression of MVED versus GLS showed a negative correlation of an $r = -0.65$ and $p < 0.001$ for the total sample and an $r = -0.53$ and $p < 0.005$ for patients with AVD (Figure 5). MVED is positively correlated with LVEF and showed an $r = 0.57$ and $p < 0.001$ for all participants.

The evaluation of VDS and VDS/MVED with GLS and LVEF

The criteria for defining concentric hypertrophy are LV mass/EDV ratio > 1.16 g/mL. Ref. Dweck MR et al. J Cardiovasc Magn Reson 2012.

showed weak correlations or discrete associations, some of which were not statistically significant for the total sample or patients with AVD (Table 3).

Table 4 shows the diagnostic performance analysis data for MVED, MD, VDS, and VDS/MVED measures to predict GLS and LVEF. MD and MVED again demonstrated better diagnostic performance than LVEF and GLS. The MD versus GLS longitudinal axis presented an area under the ROC curve of 0.88. When the best cutoff point (-0.13) was defined, MD demonstrated 72.43% sensitivity and 86.65% specificity

(Figure 6). The analysis with LVEF showed an area of 0.70, sensitivity of 75.00%, and specificity of 72.97% (at the best cutoff point under the ROC curve, -0.11) (Figure 6). MVED versus GLS showed an area of 0.91, sensitivity of 57.14%, and specificity of 87.10% (cutoff point of 0.53). The analysis of MVED and LVEF resulted in an area of 0.82, sensitivity of 50.00%, and specificity of 78.38% (at the best cutoff point of 0.61) (Figure 7). VDS and VDS/MVED demonstrated inferior diagnostic performance (Table 4).

Discussion

This study demonstrated that the assessment of LV diastolic

dysfunction using linear CMRI parameters (MD and MVED) has statistically high correlation and diagnostic accuracy to that of GLS measured by FTI and LVEF in patients with AoS and AoI as well as in normal controls.

These data corroborate and reinforce the results of the study by Ribeiro et al., in which LV linear measurements

(MVED, MD, VDS, and VDS/MVED) differed significantly between patients with AVD and normal controls. In our study, we validated linear measurements derived from LLD versus GLS measured by specific FTI software and LVEF. Saba et al. used a similar technique and obtained slightly higher linear measurements in the normal control group than in that of our study (-0.165).⁹ This is probably due to the use of a less lateral anatomical landmark and, therefore, a lower diastolic value of this distance that results in a greater percentage variation with the systolic linear measurement. The most lateral point chosen in the present study increased the precision and reproducibility of its visual definition by the observer. On cine-MRI, coronary sinus interface in the atrioventricular groove is better defined than the junction of the mitral valve leaflets in the mitral fibrous annulus. We used only one AVJ displacement measurement, with a better defined reference point on the AVJ lateral wall instead of two, thus simplifying and making the measurements faster and more practical.

Saba et al. validated linear measurements with peak systolic strain using tissue Doppler to assess diastolic function; however, our study demonstrated a statistically significant correlation between MD and GLS by FTI CMRI. These data reinforce the relevance of MD on CMRI in the assessment of systolic dysfunction. Furthermore, the area under the ROC curve of MD versus GLS showed high accuracy (0.88) for assessing systolic function. MVED demonstrated high accuracy when correlated with GLS (0.91). For the first time, this information allows the use of a method to analyze

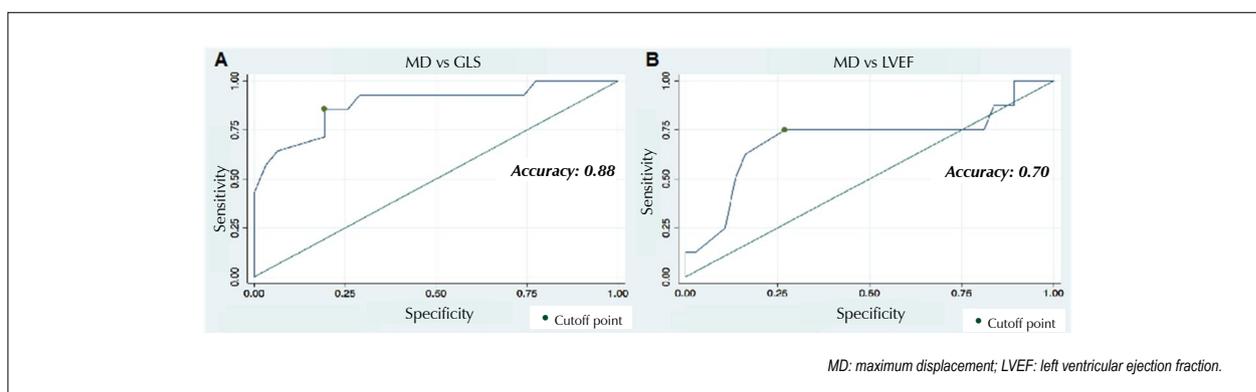

Figure 6 – (A) Receiver operating characteristic curve between global longitudinal strain and maximum velocity in early diastole indicating the best cutoff point. (B) Atrioventricular junction velocity in diastasis and left ventricular ejection fraction performance.

diastolic function by CMRI that, associated with its practical performance of both MD and MVED, can be considered a promising method for routine clinical use.

AVD presents with diastolic function disorders that precede evident LV systolic function changes that have important implications for morbidity and mortality before and after aortic valve replacement.^{13–15} Several studies reported that LVEF is not affected early in groups of patients with AVD. A deteriorated ejection fraction in the clinical setting was considered a sign of severe and advanced AVD.^{16–18} Several studies reported changed GLS and preserved LVEF in patients with AVD.^{19–22}

GLS analysis after aortic valve replacement detected improved LV diastolic function measured by transmitral flow on ECHO. Similar studies also showed that GLS analysis after valve replacement indicated improved ventricular function.²³ GLS also showed less dependence on hemodynamic load conditions than LVEF, thus detecting more subtle changes in the underlying myocardial substrate.^{24–26} Greater sensitivity for diagnosing diastolic dysfunction was observed after GLS evaluations in patients with AoS and AoI compared with conventional methods.²⁷ Analysis of the diagnostic performance of LLD parameters (MD and MVED) detects diastolic dysfunction in patients with AVD versus normal controls with

a sensitivity similar to that of GLS. Diastolic function is rarely evaluated on CMRI because it depends on mitral, pulmonary vein, and myocardial flow velocity acquisition by cine-MRI with flow map (phase-contrast). Simple and practical MD and VDS measurements, especially the latter, represent a promising option for the diagnosis of diastolic dysfunction by CMRI that was validated in this study for patients with AVD.

VDS measurements and the VDS/MVED ratio also showed significant differences between pathological patients and normal controls, providing additional data in the assessment of diastolic dysfunction. However, the differences were smaller compared to those of MD and MVED, probably indicating less potential for their clinical application.

Limitations

This was a retrospective study with a relatively small number of patients. We also did not correlate LLD and GLS by ECHO; however, these parameters were validated by the CMRI myocardial tagging, a technique similar to the FTI used in this study as a reference, which mitigates this limitation. Finally, our new LLD method was validated only in patients with AVD; thus, future studies are needed to validate its use in patients with other diseases.

Conclusion

This study validated the LLD technique against GLS measured by FTI using CMRI. LLD parameters were obtained using only two linear measurements, which is possible with most image visualization software. Of the LLD parameters that assess systolic-diastolic function, MD showed better accuracy for assessing systolic function (normal values, less than -0.13), while MVED showed better accuracy for assessing diastolic function by CMRI (normal values, greater than 0.66). These parameters can improve the assessment of systolic-diastolic contractility in the clinical CMRI routine.

Is Paclitaxel Less Cardiotoxic in the Treatment of Breast Cancer Before or After Doxorubicin?

Qual Estratégia Terapêutica é Menos Cardiotoxica no Tratamento do Câncer De Mama: Uso de Paclitaxel Antes ou Depois da Doxorubicina?

Abstract

Background: The combination of doxorubicin (DOX) with paclitaxel (PTX) effectively treats breast cancer (BC). However, DOX-associated cardiotoxicity (CTX) is aggravated by the use of PTX. Consensus is lacking about which drug sequence involves the most CTX.

Objectives: To evaluate whether DOX followed by PXT or the reverse sequence has the greatest cardiotoxic potential in the treatment of BC.

Methods: Prospective study of women with primary BC who received four cycles of DOX and 12 infusions of PTX. Participants were divided into Group 1 (G1; PXT before DOX) and Group 2 (G2; DOX before PXT) at the discretion of the oncologist. CTX was defined as an absolute reduction in left ventricular ejection fraction (LVEF) > 10% to a value <53%. Patients underwent clinical evaluations and echocardiography before treatment (Phase 1) and one year after treatment (Phase 2).

Results: Sixty-nine women were evaluated: 19 in G1 and 50 in G2. The groups had similar clinical characteristics. The doses of radiation, DOX, and PTX used were similar. Eight (11.6%) patients developed CTX: two (10.5%) in G1 and six (12.0%) in G2 ($p=0.62$). The mean LVEF was similar between groups in Phase 1 ($G1=65.1\pm 3.5\%$; $G2=65.2\pm 3.9\%$; $p=0.96$), with a significant reduction noted after one year in both groups: $G1=61.4\pm 8.1\%$ ($p=0.021$) and $G2=60.8\pm 7.6\%$ ($p<0.001$). Although lower, mean LVEF remained similar between groups after Phase 2 ($p=0.79$).

Conclusions: In women with BC who underwent chemotherapy, the incidence of CTX at the end of the first year of treatment was similar regardless of whether DOX was used before or after PTX.

Keywords: Cardiotoxicity, Paclitaxel, Doxorubicin, Breast neoplasm.

Resumo

Fundamento: A combinação de doxorubicina com paclitaxel é eficaz no tratamento do câncer de mama. No entanto, a cardiotoxicidade associada à doxorubicina é agravada pelo uso do paclitaxel. Não há consenso sobre qual sequência é mais segura.

Objetivos: Avaliar qual sequência tem maior potencial cardiotoxico no tratamento do câncer de mama: doxorubicina seguida de paclitaxel ou o inverso.

Métodos: Estudo prospectivo de mulheres com câncer de mama primário. Todos os participantes receberam quatro ciclos de doxorubicina e 12 infusões de paclitaxel. Os participantes foram divididos em dois grupos, a critério do oncologista: Grupo 1, que recebeu paclitaxel antes da doxorubicina, e Grupo 2, que teve doxorubicina antes do paclitaxel. Definiu-se cardiotoxicidade como uma redução absoluta na fração de ejeção ventricular esquerda >10% para <53%. Os pacientes foram submetidos a avaliação clínica e ecocardiografia antes do tratamento (fase 1) e 1 ano após o tratamento (fase 2).

Resultados: Foram avaliadas 69 mulheres: 19 no Grupo 1 e 50 no Grupo 2. Os grupos apresentavam características clínicas semelhantes. As doses

de radiação, doxorubicina e paclitaxel utilizadas foram semelhantes. Oito (11,6%) pacientes desenvolveram cardiotoxicidade: dois (10,5%) no Grupo 1 e seis (12,0%) no Grupo 2 ($p=0,62$). A fração de ejeção ventricular esquerda se mostrou semelhante entre os grupos da fase 1 (Grupo 1 = $65,1 \pm 3,5$; Grupo 2 = $65,2 \pm 3,9$; $p=0,96$), com redução significativa após 1 ano em ambos os grupos: Grupo 1 = $61,4 \pm 8,1\%$ ($p=0,021$) e Grupo 2 = $60,8 \pm 7,6\%$ ($p<0,001$). Embora menor, a fração de ejeção ventricular esquerda permaneceu semelhante entre os grupos após a Fase 2 ($p=0,79$).

Conclusão: Nas mulheres com câncer de mama submetidas à quimioterapia, a incidência de cardiotoxicidade ao final do primeiro ano de tratamento foi semelhante, independentemente do uso de doxorubicina antes ou após o paclitaxel.

Introduction

Approximately 1.7 million new cancer cases will be diagnosed in the United States in 2019. Of them, 270,000 will be breast cancer (BC)^{1,2}. In Brazil, the National Cancer Institute estimates approximately 600,000 new cases of cancer in 2019, including 60,000 of BC³. From 1991 to 2016, the overall cancer mortality rate steadily declined in the US by 27%, translating into approximately 2.6 million fewer cancer deaths than would be expected had mortality rates remained at their peak². The mean 5-year survival rate of patients with BC is approximately 90%². The causes of this improvement in survival are multifactorial. Advances in antineoplastic therapy play an important role in this favorable outcome, but this type of therapy is also associated with undesirable cardiotoxic effects⁴.

Doxorubicin (DOX) and paclitaxel (PTX) are potent chemotherapeutic drugs that were introduced in the therapeutic arsenal in the 1960s and 1980s, respectively⁵. The combination of DOX with PTX is widely used in BC patients because of its efficacy against cancer cells⁶. DOX is a chemotherapeutic agent of the anthracycline class that, depending on the dose used, may feature left ventricular (LV) dysfunction as a side effect in 3–48% of cases⁴. PTX and DOX belong to the taxane class (antimicrotubule agents), which have an incidence of cardiotoxicity (CTX) of 1–13%⁴. DOX-associated CTX is aggravated by PTX use^{6–10}. In experimental study models, PTX may synergistically aggravate DOX-induced CTX. This result is reportedly more pronounced when PTX is used 24 hours after DOX¹¹. Data from the FinHer trial, in contrast, suggested that CTX may remain low when a taxane (docetaxel) is given prior to the anthracycline¹². Whether due to the therapeutic benefits or possible side effects, consensus is lacking about which drug should be used first in the treatment of BC patients^{6,13}.

Echocardiography is an important tool in the follow-up of patients who are antineoplastic therapy candidates. In this scenario, left ventricular ejection fraction (LVEF) is the most commonly used echocardiographic parameter for monitoring ventricular function¹⁴. Although useful, LVEF has low sensitivity for detecting small changes in ventricular function. The evaluation of myocardial deformation through the study of strain by the speckle tracking technique allows detection of subclinical LV dysfunction in several scenarios¹⁵. The reduction in global longitudinal strain (GLS) in patients undergoing chemotherapy is a sign of subclinical myocardial alterations that occur secondary to cancer therapy¹⁶. The change in GLS in this scenario usually occurs before any change in LVEF is detected^{16,17}.

The primary objective of this study was to evaluate which sequence has greater cardiotoxic potential in the treatment of BC patients: DOX followed by PTX or the reverse order. The secondary objective was to evaluate GLS and LVEF at the end of the first year of treatment of BC patients undergoing chemotherapy and compare GLS and LVEF between the DOX and PTX use sequences.

Methods

This prospective study included women diagnosed with BC indicated for treatment with DOX and PTX who were admitted to the oncology service of our hospital for chemotherapy during the period of 06/2014 to 07/2015. The exclusion criteria were an LVEF < 55%, previous cancer treatment, segmental dysfunction detected on echocardiography, diagnosis of heart failure by the Framingham criteria, inadequate echocardiographic window for GLS analysis, complex arrhythmia, valvular heart disease, any type of cardiomyopathy, and LV hypertrophy greater than discrete. All patients received four cycles of DOX (60 mg/m²) with intervals of three weeks between cycles and 12 weekly infusions of PTX (80 mg/m²). The sequence of use of both drugs was at the discretion of the treating oncologist. Participants were divided into Group 1 (PTX before DOX) and Group 2 (DOX before PTX). Patients underwent clinical evaluation and echocardiography prior to treatment initiation (Phase 1) and one year after initiation of DOX (Phase 2). CTX was defined as an absolute reduction in LVEF > 10%, to a value < 53%, one year after starting DOX¹⁴. The study was approved by our institution's research ethics committee. All patients signed an informed consent form.

Echocardiography

Transthoracic echocardiography was performed using a Vivid 6 or Vivid I cardiovascular ultrasound system (GE Healthcare, Milwaukee, WI, USA). All echocardiographic variables were analyzed off-line at the workstation of our service's echocardiography laboratory. EchoPAC software version 112.0.x (GE Healthcare) was used for these analyses. LVEF was calculated using the modified biplane Simpson method with four- and two-chamber apical views of the LV. The other echocardiographic measurements were calculated based on American Society of Echocardiography guidelines¹⁸.

Grayscale images of the two-dimensional echocardiograms were obtained in four-, three-, and two-chamber apical views for the measurement of the LV subjective global assessment (SGA). The aortic valve closure time was obtained using pulsed Doppler flow tracing in the aortic valve synchronized with the electrocardiogram.

The professionals involved in the strain image acquisition received previous training to ensure the acquisition of adequate images for GLS analysis. The images corresponding to the GLS measurement were acquired with a frame rate of 50–80 cycles/s in three total cycles for each image. Proper tracking of points was checked and adjusted manually if necessary.

The LV SGA was calculated by the mean longitudinal strain values in the basal, mid-, and apical segments obtained in the four-, three-, and two-chamber LV apical views (Figure 1). To avoid confusion and following previous recommendations, GLS is expressed as the absolute value (aGLS), thus eliminating the negative sign^{18,19}.

Reproducibility

To determine intraobserver variability, echocardiograms from 20 randomly selected patients were retested by the same evaluator (FTAA) six months after the initial analysis. To determine interobserver variability, the data of these 20 patients were analyzed by a second evaluator (VRBBX) using the same exams and the same cycles for each.

Statistical analysis

The statistical analysis was performed using SPSS 2.0. The distribution of the studied variables was analyzed using the Shapiro-Wilk test. Quantitative variables are expressed as mean \pm standard deviation and were compared by the *t* test for independent samples or Wilcoxon signed-rank test, while qualitative variables are expressed as frequency and percentage and were compared by the chi-square test or Fisher's exact test. The paired *t* test was used to determine if the mean of the differences between two paired samples differed from zero. The interobserver and intraobserver agreements were evaluated by the intraclass correlation coefficient (ICC) with 95% confidence interval (CI). Values of $p < 0.05$ were considered statistically significant.

RESULTS

Sample

A total of 76 women with BC were treated with DOX and PTX during the study period. Of them, seven were excluded:

two who requested exclusion and five who died before the evaluation in Phase 2 (two of sepsis, one of brain metastasis, one of sudden death, and of unknown cause). Of the 69 patients who composed the sample, 19 (27.5%) were treated with PTX before DOX (Group 1) and 50 (72.5%) were treated with DOX before PTX (Group 2).

The patients' main characteristics are summarized in Table 1. At the start of the study, the two groups were similar in age, systolic blood pressure, diastolic blood pressure, body mass index, and waist circumference. The same was observed in terms of the main cardiovascular risk factors and the use of cardiovascular drugs.

Table 1 – Patient characteristics by group.

Variable	Group 1 (n=19)	Group 2 (n=50)	P value
Age (years)	50 \pm 13	49 \pm 13	0.76
SBP (mmHg)	133 \pm 18	131 \pm 26	0.79
DBP (mmHg)	83 \pm 12	81 \pm 13	0.63
BMI (kg/m ²)	26.9 \pm 5.1	27.3 \pm 4.7	0.74
Waist circumference (cm)	90 \pm 12	88 \pm 14	0.71
Cardiovascular risk factors, n (%)			
Hypertension	9 (47)	20 (41)	0.63
Diabetes	4 (21.1)	4 (8.5)	0.21
Smoking	0 (0)	3 (6.5)	0.55
Sedentary lifestyle	15 (83.3)	36 (81.8)	1.0
Dyslipidemia	1 (5.3)	3 (6.5)	1.0
Radiation therapy	16 (84.2)	40 (80)	1.0
Trastuzumab	3 (15.8)	14 (28)	0.36
Cardiovascular medication, n (%)			
ACEI	2 (13.3)	8 (22.2)	0.70
Beta-blocker	0 (0)	2 (5.6)	1.0
ARB	5 (33.3)	5 (13.2)	0.09
Antineoplastic treatment (n of doses)			
DOX (mg/m ²)	240 \pm 11	237 \pm 14	0.38
PTX (mg)	1570 \pm 138	1567 \pm 236	0.96
Radiation (Gy)	58 \pm 5	56 \pm 6	0.39

Continuous variables are presented as mean \pm standard deviation, while categorical variables are shown as frequency (percentage). ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BMI, body mass index; DBP, diastolic blood pressure; DOX, doxorubicin; PTX, paclitaxel; SBP, systolic blood pressure.

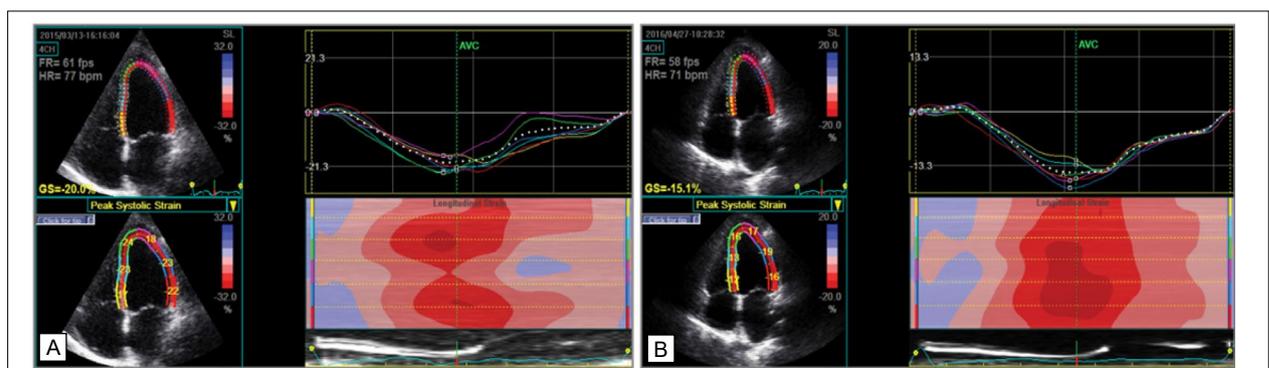

Figure 1 – Normal longitudinal strain before chemotherapy (A) and decreased longitudinal strain after chemotherapy (B).

One patient (1.4%) in Group 2 had bilateral BC. Of the others, 34 (49.3%) had right BC, and 34 (49.3%) had left BC. Seven (37%) Group 1 patients had right BC, while 27 (54%) Group 2 patients had right BC ($p=0.18$).

Eight patients (11.6%) developed CTX by the end of the study: two (10.5%) in Group 1 and six (12.0%) in Group 2 ($p=0.62$) (Figure 2).

Antineoplastic treatment

The cumulative dose of DOX and the total dose of PTX did not differ between groups ($p=0.38$ and $p=0.96$ for Groups 1 and 2, respectively; Table 1).

Radiation therapy was used in 16 (84.2%) patients in Group 1 and 40 (80%) patients in Group 2 ($p=1.0$). There was no intergroup difference in the radiation dose used ($p=0.39$; Table 1).

Seventeen (24.6%) patients were classified as being HER2-positive and, therefore, were treated with trastuzumab: 3 (15.8%) in Group 1 and 14 (28%) in Group 2 ($p=0.36$; Table 1).

Echocardiographic variables

The main echocardiographic variables in Phases 1 and 2 are presented in Table 2.

LVEF at baseline was similar between groups (Group 1, $65.1 \pm 3.5\%$ versus Group 2, $65.2 \pm 3.9\%$; $p=0.96$; Table 3). There was a significant decrease in LVEF after one year in both groups (Table 2). The LVEF decreased by 3.7% in Group 1 (from $65.1 \pm 3.5\%$ to $61.4 \pm 8.1\%$; $p=0.021$) and by 4.4% in Group 2 (from $65.2 \pm 3.9\%$ to $60.8 \pm 7.6\%$; $p<0.001$). One year after treatment, although lower, LVEF remained similar between groups (Group 1, $61.4 \pm 8.1\%$ versus Group 2, $60.8 \pm 7.6\%$; $p=0.79$; Table 3).

The aGLS results were similar to the LVEF results. There was no intergroup difference in aGLS before treatment (Group 1, $19.9 \pm 2.0\%$ versus Group 2, $20.0 \pm 2.4\%$; $p=0.90$; Table 3). A significant decrease in aGLS was noted in both groups at the end of the first year of chemotherapy (Table 2), but the decreases were similar between them (Table 3).

Other variables associated with LV systolic function (mitral annular plane systolic excursion [MAPSE], mitral S' wave, and systolic longitudinal strain rate [LSRs]) followed the same pattern as LVEF and aGLS (Table 2). The same occurred in the ratio of early diastolic transmitral velocity-to-early diastolic tissue velocity ratio (E/E' ratio), a variable related

Table 2 - Echocardiographic parameters by group and study phase.

Variable	Group 1 (n=19)		Group 2 (n=50)	
	Phase 1	Phase 2	Phase 1	Phase 2
LVDD (mm)	44.7±3.8	44.2±5.6	44.8±3.9	45.5±4.8

aGLS, absolute global longitudinal left ventricular strain; LSRs, systolic longitudinal strain rate; LVDD, left ventricular diastolic diameter; LVSD, left ventricular systolic diameter; LVEF, left ventricular ejection fraction; MAPSE, mitral annular plane systolic excursion. * $p<0.05$ versus Phase 1 results. † $p<0.05$ versus Phase 1 results.

Table 3 - LVEF and global longitudinal strain.

Variable	Group 1 (n=19)	Group 2 (n=50)	P value
Phase 1, %			
LVEF (%)	65,1±3,5	65,2±3,9	0,96
aGLS (%)	19,9±2,0	20,0±2,4	0,90
Phase 2, %			
LVEF (%)	61,4±8,1	60,8±7,6	0,79
aGLS (%)	18,4±2,3	18,9±2,7	0,48

Data are presented as mean ± standard deviation. aGLS, absolute global longitudinal strain of the left ventricle; LVEF, left ventricular ejection fraction

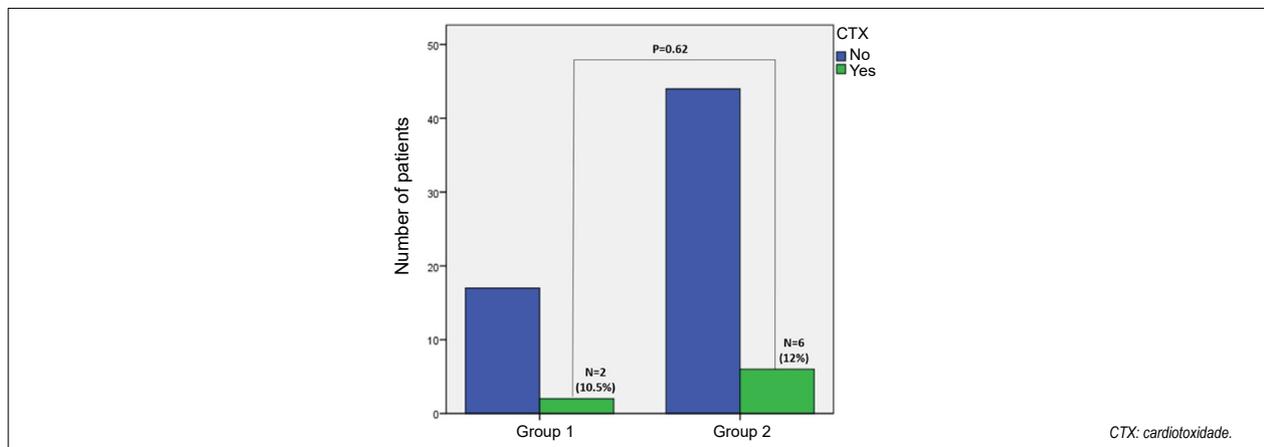

Figure 2 – Cardiotoxicity after 1 year.

to LV diastolic function. However, no change was noted in the early-to-late diastolic transmitral flow velocity ratio (E/A ratio) of mitral flow.

Reproducibility

There was excellent intraobserver agreement in aGLS (ICC, 0.94; 95% CI, 0.84–0.98) and interobserver (ICC, 0.92; 95% CI, 0.80–0.97).

Discussion

The present study demonstrated no difference in the incidence of CTX when DOX followed PTX or, conversely, when PTX followed DOX in the treatment of BC patients. Despite this, a significant decrease in aGLS and LVEF was noted at the end of the first year of chemotherapy. This decrease, however, was similar between the two groups regardless of the drug use sequence.

Other variables evaluated in our study, such as MAPSE, mitral annulus *S'* wave, and LSRs, followed the pattern observed for LVEF and aGLS. These data confer greater robustness to our results because they also provide important information about LV systolic function.¹⁴ In addition, because it is not possible to evaluate aGLS by using the speckle tracking technique, MAPSE and mitral annulus *S'* wave are the variables recommended to ensure an adequate evaluation of LV longitudinal function¹⁴.

DOX-associated CTX is aggravated by PTX treatment^{6–9}. The latter increases the plasma concentration of the former^{8,9}. PTX also stimulates the formation of DOX metabolites, which play a key role in the mechanism of CTX⁹. The effect of PTX on DOX metabolites can reportedly be attributed to interference by the PTX carrier in the biliary elimination of the anthracycline molecule, explaining the greater toxicity of the PTX-DOX association versus DOX alone⁷. Studies in laboratory animals have shown that PTX can aggravate DOX-induced CTX, especially when a taxane (paclitaxel) is used after DOX¹¹. Another chemotherapeutic taxane, docetaxel, has effects similar to those of PTX⁹. However, the FinHer study showed that docetaxel, when used before DOX, was associated with low CTX rates¹². Focan et al.²⁰ demonstrated that the use of an anthracycline (epirubicin) on day 1 followed by a taxane (PTX) on day 2 decreased the risks of hematological complications, especially neutropenia. However, the CTX, as in our study, did not change regardless of drug sequence²⁰.

The incidence of CTX in our sample was low (11.6%), similar to the 9% reported by Cardinale et al.²¹ but lower than those of other reports in the literature^{4,22}. This relatively low incidence of CTX may be attributed to the low dose of DOX used by our patients (238 ± 13 mg/m²). Higher rates are usually seen with higher doses. The increase in CTX related to the DOX-PTX combination is currently prevented by limiting the cumulative dose of DOX to 360 mg/m² or separating the infusion of the two drugs by an interval of more than four hours⁸; both approaches were used with our patients. Our patients were at low risk of developing CTX, and some were already using cardioprotective drugs. These factors may also be associated with the low incidence of CTX in our sample.

The use of more sensitive methods for detecting subclinical ventricular dysfunction, such as GLS, has been very useful for monitoring patients undergoing chemotherapy¹⁴. The data are very consistent regarding the diagnostic value of GLS in CTX screenings among these patients. A relative reduction in aGLS > 15% compared to baseline is strong evidence of subclinical ventricular dysfunction in patients undergoing chemotherapy; furthermore, it is a predictor of an LVEF decrease and subsequent development of heart failure¹⁴. Charbonnel et al.²³ demonstrated that even at low doses of DOX (150 mg/m²), aGLS was an independent predictor of future CTX associated with anthracycline use. Our study demonstrated a decrease in aGLS at one year after the start of DOX treatment, a finding that did not depend on the sequence of DOX and PTX use. The patients who composed the sample in our study continue to be followed up to enable the future analysis of the prognostic value of aGLS in patients at high risk for cardiovascular events.

The choice of the sequence of anthracycline and taxane administration in BC patients is currently based on classical biological factors as well as clinical and demographic factors associated with the risk of disease recurrence⁶. It is customary to use an anthracycline followed by a taxane based on the above information and on historical development, as anthracyclines were introduced first in clinical practice. This influences the routine of many services. However, recent studies reported using taxanes before anthracyclines²⁴, which has served as an example for other centers. Virtually all of these studies had the main objective of evaluating the therapeutic efficacy of the drugs; in most of them, there was no specific design to evaluate the cardiotoxic potential associated with the anthracycline and taxane administration sequences. Focan et al.²⁰ was one of the few that made this evaluation; epirubicin was the anthracycline used. Our study also performed this evaluation, but we used DOX instead. Based on our results, either sequence of DOX and PTX administration is safe from a cardiovascular standpoint since neither increases the risk of CTX in patients with BC. This information can give peace of mind to oncology services when choosing the treatment sequence. However, further studies are needed with larger numbers of patients that use the currently recommended doses and evaluate the CTX potential of possible anthracycline and taxane administration sequences in BC patients.

Limitations

Our study has some limitations. Its relatively small number of patients may have contributed to the lack of statistically significant intergroup differences. As the number of patients who developed CTX was small, our findings require confirmation in a larger sample. The fact that the patients come from a single center raises the possibility of selection bias. This issue is attenuated by the fact that the sample comprised all the women who met the study inclusion criteria within one year and were admitted to our hospital's oncology department for chemotherapy. Due to the variability in GLS among the different manufacturers of echocardiography devices, we cannot guarantee that our results can be replicated with devices of brands other than

the one used here. The professionals who acquired the echocardiogram images were not blinded to the examination phase, which may have led to observation bias. And finally, it was not possible to measure biomarker levels, but this was not the objective of our study.

Conclusion

In the present sample of BC patients referred to begin chemotherapy, the incidence of CTX at the end of the first year of treatment was similar regardless of whether DOX was used before or after PTX. The study also showed significant and similar decreases in aGLS and LVEF at the end of the first year of treatment regardless of the chemotherapeutic agent use sequence.

Assessing Myocardial Viability in Clinical Practice

Viabilidade Miocárdica na Prática Clínica

Miriana Basso Gomes^{1,2,3}

¹Institute of Cardiology/University Foundation of Cardiology, Porto Alegre, RS, Brazil. ²Master's student at the Postgraduate Program in Health Sciences: Cardiology and Cardiovascular Sciences at the Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil. ³Cardionuclear Clinic, Porto Alegre, RS, Brazil.

Abstract

Although assessing myocardial viability is a common cardiology practice, many physicians question the results of diagnostic methods. Nuclear medicine plays an important role in viability studies, but the reports require interpretation in a clinical and pathophysiological context. This article was aimed at reviewing the origin and evolution of myocardial viability. Here we present diagnostic methods by emphasizing nuclear medicine and provide a functional explanation of each test type using example images. We also propose how to act in these cases based on clinic examination findings, the percentage of affected myocardium, and coronary lesion topography (proximal or distal).

"Do not declare that the stars are dead just because the sky is cloudy."

Arabic proverb

Introduction

The most common question in the cardiologist's daily routine regarding interventions in patients with a previous history of infarction or left ventricular dysfunction is as follows: Is the myocardium viable or unviable? However, answering this question is not so simple. In addition to a variety of methods of assessing viability, there are several anatomical possibilities for lesions within the same muscle area. Cases referred by the physician for a viability test are usually complex to diagnose. As René Descartes said: "There are no easy methods to solve difficult problems." Thus, this review aimed at explaining the principles of viability, especially those used in nuclear medicine tests.

Theoretical background

The concept of myocardial viability emerged in the early 1980s. Prior to that point, left ventricular dysfunction was considered an "irreversible" process. The term "hibernating myocardium" was created after the perception that some patients had improved ejection fractions after coronary artery bypass graft surgery.¹

An important study at that time was the Coronary Artery Surgery Study (CASS),² which divided 780 three-vessel disease patients with left ventricular dysfunction into two treatment groups: 1) clinical and 2) surgical. The CASS study showed a significant advantage of surgical therapy. The survival rate was 88% for the surgical group versus 65% for the clinical group ($p = 0.009$). The pharmacological treatment used at the time of the CASS included no beta-blockers, statins, and angiotensin-converting-enzyme (ACE) inhibitors; moreover, no mammary grafts were used (only saphenous). Thus, the results cannot be fully extrapolated to the present day, although the concept of left ventricular dysfunction and three-vessel disease are still considered by many as synonymous with surgical therapy.

But why do patients with coronary lesions develop left ventricular dysfunction? Contractility loss is part of what we call "programmed cell survival."² The decreased blood flow decreases oxygenation and the cell increases its anaerobic metabolism to survive. Scarce adenosine triphosphate (ATP)³ (energy) is recruited to maintain vital functions and not contractility. ATP use in the myocyte is divided into 60% for systolic function, 15% for diastolic function, 5% for electrical activity, and 20% for cell membrane integrity.³

The so-called hibernating myocardium ceases contractility but maintains cellular metabolism.⁴ The muscle reduces its contraction as a protective factor to consume minimal energy and prevent cell death. A histological analysis of hibernating myocardium demonstrated non-contractile myocytes with intact membranes and little or no evidence of metabolic apoptosis.⁴ The stunned myocardium is also a mechanism of programmed cell survival, being characterized by contractile dysfunction that follows brief episodes of myocardial ischemia after blood flow has been restored.⁵ Briefly, hibernation is a protective phenomenon that reduces contractility in the setting of a persistently decreased blood flow. On the other hand, stunned myocardium is a consequence of injury in cases in which contractility remains temporarily reduced despite the return of coronary flow.

It is not always simple to differentiate hibernated from fibrotic myocardium through tests. Each method assesses it according to the following principles of viability⁴:

Presence of myocardial blood flow

Myocardial blood flow can be assessed by capturing ^{99m}technetium-2-methoxyisobutyl-isonitrile (^{99m}Tc-MIBI).⁶ MIBI (sestamibi) is a monovalent cation that along with ^{99m}Tc, forms a radiopharmaceutical that lodges in the mitochondria of myocardial cells. The retention of this tracer in intact mitochondria reflects viable myocytes. In cases of decreased cardiac uptake with ^{99m}Tc-MIBI, imaging can be acquired after the administration of nitrate to improve perfusion with

vasodilator stimulation.⁷ ^{99m}Tc-MIBI is not the best method for assessing viability, as viable regions with low blood flow can be misclassified as scars (Figure 1).

Cell membrane integrity

Cell membrane integrity can be assessed using thallium (on single photon emission computed tomography) and rubidium (on positron emission tomography [PET]) scans, which have a physiology similar to potassium ion. Thallium is not a radiopharmaceutical like ^{99m}Tc-MIBI but rather a radioisotope produced in cyclotron. The physical half-life of thallium-201 is 73 hours. The sodium-potassium pump acts on the cell membrane, enabling the assessment of its integrity through these substances, which are analogous to potassium.⁸ Potassium, the main intracellular cation, is absent in scar tissue. As thallium does not bind to organelles within myocytes, it is pushed out of the cell by the same entry mechanism. Thallium excretion from the cell is called redistribution. In this process, normal tissues redistribute thallium faster than ischemic tissues. Therefore, most thallium protocols include only one tracer injection with two image acquisitions, which can consist of rest and redistribution or stress and redistribution.

The following scenarios are possible:

- Changed rest with improved redistribution, leading to necrosis with viability.
- Changed rest without improved redistribution, leading to necrosis without viability.
- Changed stress with improved redistribution, leading to ischemia with viability.
- Changed stress without improved redistribution, leading to necrosis without viability.
- Normal stress, leading to normal test findings (no redistribution image required).

In some cases, an additional 24-hour late imaging test may be performed after a low-dose reinjection. However, this does

not happen with ^{99m}Tc-MIBI, which does not redistribute; therefore, separate injections are required for stress and rest studies at intervals of up to several days between steps.

Figure 2 shows the test performed on a patient admitted to the hospital with a history of infarction and catheterization with an occluded left anterior descending coronary artery but the presence of collaterals. The initial image taken after stress shows significant apical anterior hypoperfusion, while redistribution images show mild reversibility. As the reversibility area was small in the first acquisitions and the patient experienced symptoms and electrocardiographic changes during stress, late redistribution was performed. Normal tissues redistribute thallium faster than ischemic tissues, so perfusion improvement (viability sign) can be seen on images only after 24 hours.

Figure 3 shows a test performed with thallium-201. The top line shows rest images with hypoperfusion at the apex and distal portions of the anterior, septal, and inferior walls. The bottom line shows redistribution images (3 hours post-injection) with improved perfusion - a sign of viability.

Preserved metabolic activity

Metabolic myocyte activity can be measured by PET.⁹ In the viability protocol, the patient is injected with ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG), a glucose analog labeled with fluorine-18 when associated with a carbohydrate-free diet. In the situation of chronic ischemia of the hibernated myocardium, the oxygen supply is low and the myocardium partly uses the glycolytic (anaerobic) pathway for energy production, which may be inadequate to maintain contractility but sufficient to maintain cellular metabolism. If the patient is taking a ketotic diet (low in sugars), cellular uptake of this tracer will be low. The hibernated myocardium, unlike normal muscle, involves a chronically activated glycolytic pathway and will be able to capture ¹⁸F-FDG through its residual glucose metabolism, showing viable areas.

Figure 3 – Test using thallium-201.

The top line in Figure 4 shows a test with thallium-201 evidencing an area of perfusion defect⁴ in the territory of the anterior descending coronary artery. The bottom line shows a test with ¹⁸F-FDG evidencing increased capture⁵ and, therefore, preserved metabolism precisely in areas deficient in thallium-201. These test results are compatible with myocardial viability. Mismatch (viable myocardium) occurs when the perfusion image is changed and metabolism is improved. Match (absent viability) occurs when cases are changed in both studies and, therefore, demonstrate defect pattern agreement (Figure 5).

¹⁸F-FDG PET associated with cardiac magnetic resonance imaging (MRI) is considered the best method for detecting myocardial viability since MRI assesses the absence of myocytes using late gadolinium enhancement.¹⁰ Interpretation of the results is based on analysis of the transmural extension of the enhancement in relation to the healthy region. When the

length of the same segment is less than 50%, the myocardium is viable. When the extension of the same segment is greater than 50%, the myocardium is not viable.

Finally, viability can also be analyzed through the “contractile reserve” by dobutamine echocardiography.¹¹ Viable myocardium in this situation will have the following characteristics:

- Abnormal contractility at rest
- Improved contractility at a low dose of dobutamine
- Unchanged contractility at a high dose of dobutamine

A myocardium with ischemia and viability benefits most from revascularization. In such cases, the stress echocardiogram will have the following findings:

- Abnormal contractility at rest
- Improved contractility at a low dose of dobutamine
- Worsened contractility at a high dose of dobutamine

A viability study is not indicated in cases of a myocardium with normal contractility at rest. If there is some degree of kinesis, necrosis does not predominate. Knowledge of the concept of hibernation is essential to prevent an erroneous request for viability test based only on a previous history of infarction or some electrocardiographic changes. Table 1 summarizes the main viability assessment methods.¹²

Considerations about myocardial perfusion

Myocardial perfusion changes are not always segmented and homogeneous. Reports would be less complex if the areas

without viability were exactly in segments irrigated by a single coronary artery. However, areas of necrosis surrounded by areas of ischemia (or even normal myocardium) in the same topography are a common finding on scintigraphy. For example, a patient may have necrosis without viability in the medial and apical anterior segments that totals 12% of the extension. However, other viable areas are irrigated by the anterior descending coronary artery, such as the basal anterior segments and the entire septal wall. The attending physician may consider not revascularizing this artery since the report showed no viability. However, the territory of the anterior descending coronary artery extends beyond the 12% described; thus, this

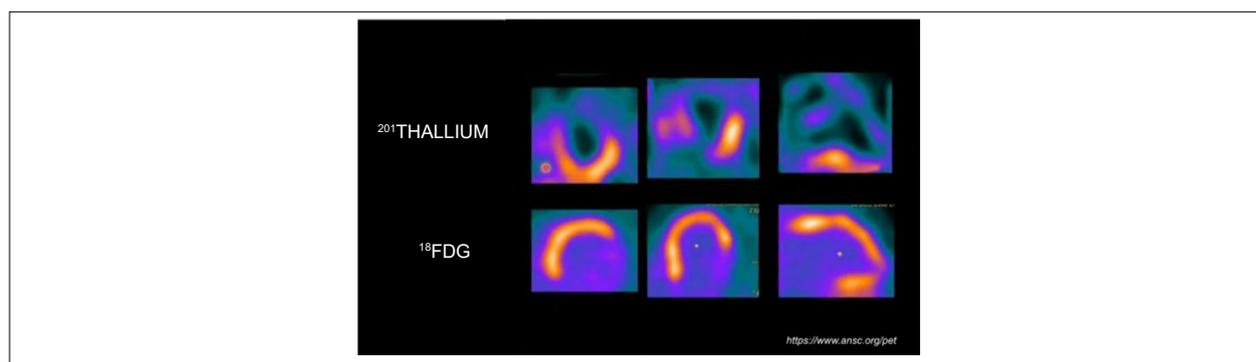

Figure 4 – Image on the top line taken with thallium-201 showing an area of necrosis in the territory of the anterior descending coronary artery.

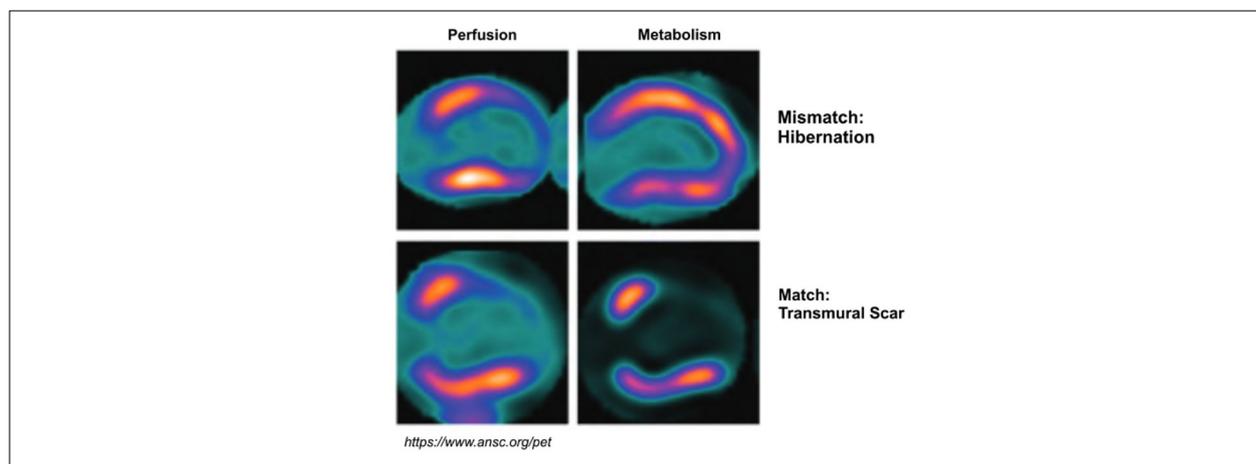

Figure 5 – Image mismatch and match.

Table 1 - Summary of the main viability assessment methods.

Methods	Radiation	Duration	Number of phases	Sensitivity	Specificity
Echocardiography with dobutamine	Absent	30 min	----	77-89%	68-93%
^{99m} Tc-MIBI SPECT	Moderate	90-120 min	2 injections	81%	69%
Resonance	Absent	35 min	2 injections	92%	51-89%
Thallium-201	Discharge	3 h with additional 24-h IN image	1 injection	87%	54%
¹⁸ F-FDG PET	Moderate	1 h	1 injection	92%	63%

¹⁸F-FDG PET, ¹⁸F-fluorodeoxyglucose positron emission tomography; SPECT, single photon emission computed tomography; ^{99m}Tc-MIBI, ^{99m}technitium-2-methoxyisobutyl-isonitrile, IN, if necessary.

decision could compromise an important part of the muscle. If we consider three territories in the left ventricular myocardium, the percentage of each main coronary artery will be about 33% of the total. Therefore, the 12% proportion without viability in this area does not represent the physiological importance of the left anterior descending coronary artery. If a patient has lesions in the three main coronary arteries, coronary artery bypass graft surgery cannot be avoided due to a non-viable area of 10–15% and viable area of more than 80%. In addition, the Stich study already showed that a lack of viability was associated with no differences between drug therapy and revascularization.¹³ The presence of viability proved to be a good prognostic factor regardless of the approach used.¹⁴

Most methods divide the myocardium into 17 segments, but there are only three main coronary arteries. Therefore, it is necessary to analyze exactly which segments are being irrigated by each of the coronary arteries in each case. Apical necrosis is a very common scintigraphic finding because tissue suffering almost always occurs firstly at the tip of the heart. When a vascular occlusion occurs in the leg, for example, fibrosis starts at the tip of the toes and may extend throughout the foot. The same occurs with the heart, justifying a high prevalence of tissue suffering in the apical region of the left ventricle.

The apical region comprises the apex (segment 17) and the distal portion of all walls (anterior, septal, inferior, and lateral).¹⁵

For example, necrosis may develop if the patient has an infarction involving medial occlusion of the anterior descending coronary artery. If short time is available to open the coronary artery, the fibrotic area is likely to be only at the apex. If the delta T is greater, this fibrosis will extend from the apex to the medial portion of the anterior wall and affect the septum.

A very relevant analysis involves determining whether the coronary lesion(s) is proximal or distal. If the patient has distal lesions and necrosis is present in the periapical segments, the absence of viability is less important even by a method that is not the gold standard, as a smaller tissue area is at risk.

However, if the patient has proximal or left main coronary

lesions, necrosis in the distal portions of the left ventricle should not be decisive for ruling out revascularization. In these cases, a stress test or analysis of clinical and electrocardiographic changes is often more important in the choice of a particular therapy than a viability test alone.

Imaging tests were performed of a patient with a history of inferior wall infarction and three-vessel lesion. The tests were performed after coronary artery bypass graft surgery and showed necrosis sequelae in the apex and lower basal segment (Figure 6).

Figure 7 shows the case of a patient with a history of anterior wall infarction and lesions in the anterior and right descending coronary arteries. A viability test quantified necrosis in 15% of the apical anterior extension (bottom line). The use of a stress test was suggested (top row) as the lesions were proximal. Perfusion worsened in the middle and basal anterior segments beyond the bottom wall. The report indicated necrosis with ischemia and viability in the territory of the anterior descending coronary artery and ischemia in the territory of the right coronary artery.

Figure 8 shows the case of a patient with lesions in the three coronary arteries and an occluded anterior descending coronary artery. A viability test was requested, but a stress test (top row) was suggested to better guide treatment.

Despite the significant area of necrosis at rest, worsening that occurs after stress indicates the presence of viable myocardial peri-necrosis. Ischemia also occurs in the other periapical segments (septal, lateral, and inferior).

Another important change is right ventricular uptake only on post-stress images as a sign of severe ischemia. These findings indicate the need for myocardial revascularization surgery.

Final messages

No imaging method can assess viability with 100% sensitivity and specificity, so if it is clinically justified, the physician should consider revascularization.

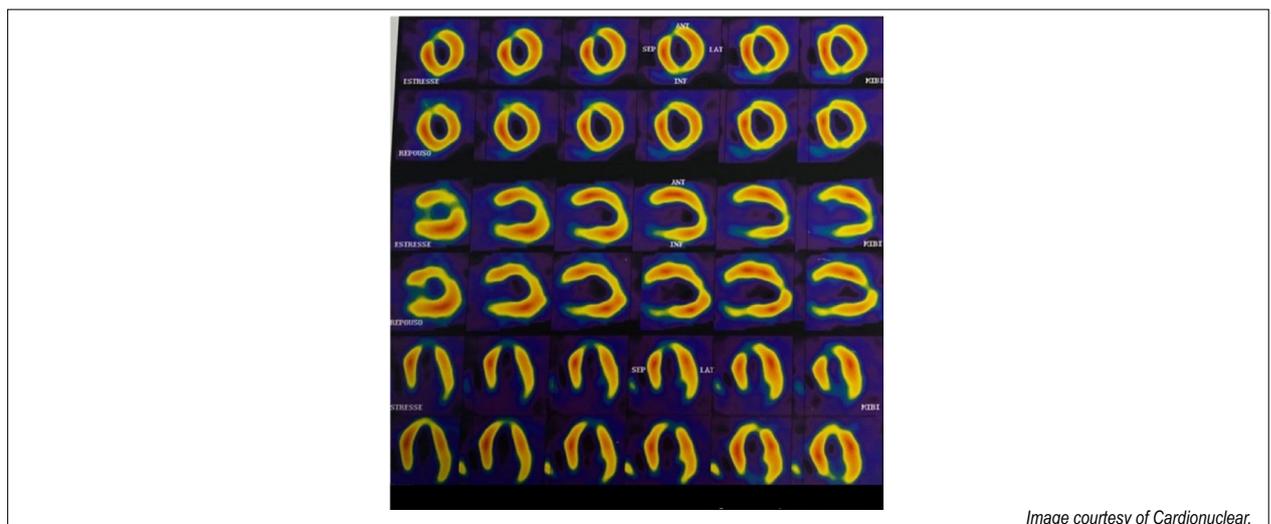

Image courtesy of Cardionuclear.

Figure 6 – Imaging tests of a patient with a history of inferior wall infarction and a three-vessel lesion.

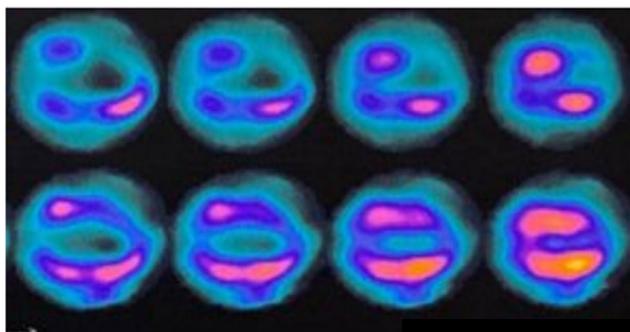

Image courtesy of Cardionuclear.

Figure 7 – Image of a patient with a history of anterior wall infarction and lesions in the anterior and right descending coronary arteries.

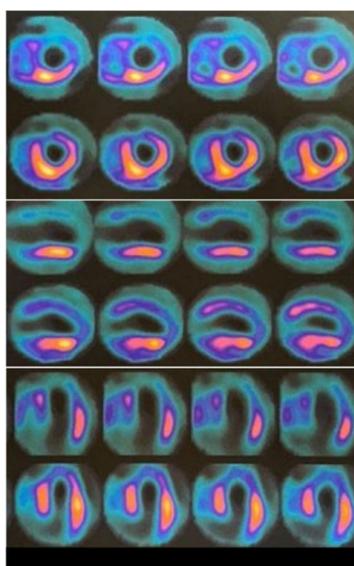

Image courtesy of Cardionuclear.

Figure 8 – Test of a patient with lesions in the three coronary arteries and an occluded anterior descending coronary artery.

The Stich study¹³ showed that the absence of viability was associated with no differences between drug therapy and revascularization. However, an analysis performed 10 years after that study showed that the ejection fraction increase was greater in patients with viability (regardless of treatment approach).¹⁶

The Christmas study also reported that patients with heart failure using carvedilol experienced a greater increase in ejection fraction when viability was present.¹⁷ Therefore, viability can be considered a useful indicator of good prognosis regardless of assessment method.

Areas with less than 30% viability should be analyzed very carefully, as each of the three main coronary territories corresponds to approximately 33% of the left ventricle. Not revascularizing a coronary artery due to a small percentage of fibrosis may compromise other segments also supplied by the same coronary artery.

When the fibrotic area is restricted to the apex and surrounding segments, it is important to analyze whether the coronary lesion(s) are proximal or distal. If they are distal, clinical treatment is indicated. If they are proximal, there is a greater tendency to perform invasive therapy due to the higher percentage of myocardium at risk, a stress test may aid in therapeutic decision.

Role of Strain in the Early Diagnosis of Diabetic Cardiomyopathy

Papel do Strain no Diagnóstico Precoce da Cardiomiopatia Diabética

Abstract

Background: Advanced echocardiography using two- and three-dimensional myocardial strain proposes to identify subclinical systolic dysfunction in different clinical conditions. Strain assessment plays an important role in the early diagnosis of diabetic cardiomyopathy in diabetes mellitus (DM). However, the findings of published articles are heterogeneous. Here we conducted a systematic review to analyze the current role of strain assessment in patients with DM. **Methods:** This systematic review of five databases identified 19 studies that used two-dimensional strain and 8 studies that used three-dimensional strain. **Results:** The studies of two-dimensional strain included 1,774 DM patients (mean age, 57.1 years; median age, 55 years; 47.5% women), while those of three-dimensional strain included 488 DM patients (mean age, 55.7 years; median age, 63 years; 51% women). Global longitudinal strain was the myocardial deformation marker that differed most frequently between the DM and control groups. **Conclusion:** Myocardial strain imaging by two- and three-dimensional speckle tracking echocardiography allows the identification of subclinical systolic dysfunction in DM patients, and differences become more marked when associated with risk factors and ventricular remodeling.

Introduction

Diabetes mellitus (DM), among the most prevalent diseases in the modern world, is a risk factor for heart failure that increases mortality, mainly from cardiovascular causes.¹ Cardiovascular complications are the leading cause of death in DM patients,^{2,3} with diabetic cardiomyopathy being characterized by structural and functional cardiac changes without other known factors for the development of myocardial dysfunction, such as coronary heart disease, arterial hypertension, or significant valvular diseases.⁴ Cardiac remodeling in diabetes results from cardiovascular autonomic neuropathy, renin-angiotensin-aldosterone system activation, interstitial myocardial fibrosis, microangiopathy, inflammatory cytokines, and metabolic changes such as hyperglycemia,^{5,6} and its detection requires sensitive diagnostic methods.⁷

DOI: 10.47593/2675-312X/20223502eabc293

The early diagnosis of diabetic cardiomyopathy is clinically relevant, as early lesions may be reversible^{8,9} and therapy can be implemented to prevent cardiovascular disease progression. However, it remains little recognized by clinicians¹ due to the conflicting results of different populations¹⁰ and the need for more sensitive and recently developed diagnostic tools. Left ventricular (LV) diastolic dysfunction was considered the initial sign on Doppler echocardiography.^{11,12} Improved imaging methods such as speckle tracking echocardiography enabled the earlier detection of systolic myocardial dysfunction prior to diastolic dysfunction in asymptomatic subjects.^{13,14}

The incorporation of new techniques such as myocardial strain on echocardiography increased the diagnostic sensitivity of speckle tracking, especially of subclinical myocardial dysfunction, and was validated by magnetic resonance imaging with myocardial tagging and sonomicrometry.¹⁵ The most commonly used parameter is global longitudinal strain (GLS), the mean strain of myocardial segments in the longitudinal direction, a technique that is more reproducible and can identify subclinical LV dysfunction, a better risk predictor than LV ejection fraction (LVEF).¹⁶ Another recent concept is multilayer analysis, which introduced an anatomical aspect into myocardial deformation assessment in which the three LV myocardial layers (endocardium, mesocardium, and epicardium) contribute to more effective contractions in different directions.¹⁷ In contrast, three-dimensional myocardial strain enables a more objective assessment of LV systolic dysfunction without requiring calculations to predict ventricular geometric shape, with the additional benefit of being more reproducible than two-dimensional strain for avoiding marker loss outside the analyzed plane despite requiring high-quality images.¹⁸

Several studies aiming to assess cardiac function in DM patients using two- and three-dimensional strain reported worse myocardial deformation rates compared to controls. However, some such studies were small, heterogeneous, and presented several confounding factors. Thus, a review of the current evidence is necessary to understand knowledge gaps and revisit important issues. The present study aimed to identify whether advanced two- or three-dimensional speckle tracking echocardiography could demonstrate early cardiac lesions secondary to DM and define its current role for assessing DM patients. Thus, here we conducted a systematic review of the use of ventricular strain echocardiography in DM.

Methods

This systematic review was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. We searched the MEDLINE,

EMBASE, SCOPUS, and WEB OF SCIENCE databases using the descriptors “diabetic cardiomyopathy” or “speckle tracking” or “myocardial strain/dysfunction” or “ventricular function/dysfunction,” “deformation imaging/analysis,” or “cardiac mechanics/function” and “diabetes” or “diabetic.” The search was limited to articles in humans; published in English, French, Spanish, or Portuguese; and published through January 31, 2022. The selection criteria for the articles were age older than 15 years, inclusion of control group without DM, no established heart disease, and speckle tracking description of the GLS value. Database references were gathered in the Mendeley® application and duplicates were removed. Two researchers (TRWS and RLS) searched the articles separately and agreed on the eligibility of the final selections. First, a broad search identified articles related to the topic by title and abstract screening. The exclusion criteria were a different target population or no control group; the presence of coronary artery disease or other structural disease; use of another imaging method for measuring myocardial deformation such as magnetic resonance imaging or tissue Doppler; no description of the GLS value; and case report, conference presentation, review, and editorial articles.

The articles were subsequently subjected to full-text review to identify those that presented the necessary data and fit the previous requirements. In studies with multiple subgroups of patients or controls, the lowest-risk subgroup was selected (Table 1). The studies were allocated to two- or three-dimensional speckle tracking groups for evaluation. The information extracted from the articles included author, year of publication, brand of equipment, study design, number of cases in the sample, age,

sex, body mass index (BMI), blood pressure levels or diagnosis of hypertension, glycated hemoglobin (HbA1c) value, LVEF, GLS, global radial strain (GRS), and global circumferential strain (GCS) (Table 2). Studies of three-dimensional strain also included global strain area (GSA) (Tables 3 and 4).

Results

We identified 819 references in the electronic databases in the previous five years, excluding 123 duplicates. Of the remaining 696 studies, we obtained 75 full articles for analysis after title and abstract screenings. Another 49 studies were excluded (Figure 1). The review included 26 articles for qualitative analysis, which were classified into two main categories: two-dimensional strain (n = 19; Table 1) and three-dimensional strain (n = 8; Table 2). Only studies with a control group were included. The articles were mostly published in English, followed by French and Portuguese. Three^{18–20} were prospective studies and the others were case-control studies.

The studies using two-dimensional strain resulted in a sample of 1,774 DM patients (mean age, 57.1 years; median age, 55 years; 47.5% women). A GE Vivid E9 ultrasound machine was most often used in these studies. The studies using three-dimensional strain resulted in a sample of 488 DM patients (mean age, 55.7 years; median age, 63 years; 51% women). All studies used the GE Vivid E9 device except for two that used an Philips iE33 ultrasound system.

Of the 19 analyzed studies, less than half excluded hypertensive patients from the DM group,^{10,18,21–24} most involved type 2 DM (DM2) patients, and only three

dysfunction has traditionally been believed to precede systolic dysfunction, subclinical systolic dysfunction detected by GLS may be the first sign of diabetic cardiomyopathy.¹⁴

GLS is the myocardial deformation marker that most frequently differs between DM and control groups. Some studies established a specific GLS value for the diagnosis of subclinical ventricular dysfunction based on the statistical analysis of the values obtained in the sample. In these studies, the incidence of subclinical ventricular dysfunction was 40–45% in the diabetic population.^{20,35} The fewer studies that used other parameters, such as GCS^{17,23,24,26} or GRS²³, identified myocardial function differences using two-dimensional strain. These differences were not detected using LVEF. Tadic et al.¹⁷

showed a GRS difference only in a DM and hypertension group. Likewise, Jørgensen et al. reported a GCS difference among subgroups of DM patients with more risk factors.³⁶

Multilayer speckle tracking analysis can show differences between DM and control groups.^{17,23,24,37} Despite being a new technology that requires further validation, this tool locates myocardial lesions and detects possible changes early.³⁸ Tadic et al. studied healthy controls, DM2 patients, and/or patients with systemic arterial hypertension (SAH) and reported multidirectional strain change; hypertension as a factor for LV mechanical deterioration; involvement of all myocardial layers due to DM and SAH; and a correlation between glycemic control (fasting glucose and HbA1c), GLS, and LV layer-specific strain.

In the previous five years, only three studies followed the participants. Studies including DM2 patients had larger sample sizes. Stevanovic et al. and Ng et al. followed up more than 100 subjects and demonstrated that GLS was a strong predictor of cardiovascular events in multivariate analysis.^{20,39} Ringle et al. evaluated a group of DM1 patients a mean 37 years of age without cardiovascular risk factors who presented an absolute strain value lower than the control population and a significantly decreased absolute strain value during follow-up; however, no events were observed in the follow-up period. This study showed no correlation between GLS and metabolic status in terms of glycemic control, diabetes duration, or coexisting microvascular complications.¹⁸

Of the 19 articles analyzed, only four^{10,31,33,36} identified no GLS differences and demonstrated subclinical myocardial function reduction attributable to diabetes. These studies analyzed DM1 and/or DM2 patients but with clearly fewer risk factors, such as SAH, overweight and obesity, dyslipidemia, renal function measured by creatinine clearance, lower glycemic levels (HbA1c < 8%), which, when present, were controlled in addition to showing no or smaller differences in LV structural parameters such as ventricular mass index and relative wall thickness. This information is useful for predicting a better prognosis for these patients and encouraging good control of comorbidities.

Several authors studied possible contributors to worsen systolic function in patients with diabetes. Yang et al. studied the relationship between microvascular complications and LV systolic function and reported decreased GLS in the group without complications that was even greater in the group with microvascular complications.²¹ Soufi et al. studied hypertensive patients with and without diabetes and showed that the association of SAH and DM further decreases ventricular systolic function when evaluated by strain and that the two independent variables for this decreased absolute GLS value were DM2 and relative posterior wall thickness.²⁵ Jørgensen et al. designed a study to assess the influence of risk factors in DM patients and reported an association between systolic blood pressure, BMI, HbA1c, and LV structure and function. Thus, risk factors should be weighed when analyzing studies that assess diabetic cardiomyopathy to avoid confounding factors. Regardless, this population has a high prevalence of comorbidities, and poor metabolic control can interfere with cardiac function.

As for glycemic control, Lind et al. analyzed 20,985 DM1 patients and concluded that even after adjusting for other cardiovascular risk factors, the risk of heart failure was still four-fold higher in patients with poor glycemic control than in those with excellent glycemic control and that each 1% increase in HbA1c corresponded to a 30% increase in the risk of developing heart failure.⁴⁰ Li et al. explored the relationship between glycemic control and LV dysfunction in DM2 patients through HbA1c³² and found that LVEF showed no difference; however, ventricular mass index and mitral E-wave velocity differed between the DM and control groups, with a greater difference in the group with worse glycemic control. In addition, there was no GLS difference between the group with good glycemic control and the control group. This study showed a correlation between HbA1c, ventricular

mass index, and E/e' ratio, and GLS. Wang et al.²² showed an intergroup difference in GLS; however, there was already an LVEF difference. This study highlights the poor glycemic control in the DM2 group prior to hospitalization, with an HbA1c value around 10%.

Contrary evidence was reported by studies that showed no difference between DM and control groups with populations with better-controlled risk factors.^{10,18,31,36} Three-dimensional speckle tracking analysis identified a lower absolute GLS value in subjects with diabetes versus controls.^{18,41–46} Depending on the associated risk factor, other parameters also showed differences, such as GCS^{42–46} and GRS.^{42,47} Chen et al. concluded that three-dimensional speckle tracking strain detects LV dysfunction in DM patients with poor glycemic control and that myocardial dysfunction is associated with DM duration and HbA1c.⁴⁶ Wang et al. demonstrated that fasting glucose, dyslipidemia, and BMI were significant risk factors for LV remodeling in DM2 patients. Those with normal ventricular geometry showed differences in only GLS compared to controls, while DM patients with LV remodeling showed lower absolute GLS, GCS, GSA, and GRS values.⁴⁴ Hepatic steatosis is another condition highly prevalent in DM2, being associated with LV remodeling and subclinical ventricular dysfunction; of the three-dimensional strain parameters, GLS presented the most evident change.⁴² Finally, intensive treatment with an insulin pump improved LV systolic function, proving a sensitive and accurate diagnostic technique that could even provide data on the therapeutic effect.⁴³

As previously reported,^{18,48} image acquisition and the analysis of myocardial deformation by three-dimensional speckle tracking was faster than that by two-dimensional speckle tracking; however, high-quality images are required to ensure an accurate strain analysis.

Conclusion

Myocardial strain imaging by two- and three-dimensional speckle tracking echocardiography enables the identification of subclinical systolic dysfunction in DM patients that becomes more marked when associated with risk factors and ventricular remodeling. The introduction of tools like the layer-specific method allows for a broader understanding of myocardial involvement in DM. Despite few prospective studies assessing clinical outcomes, there is evidence of an association between GLS and cardiovascular events in DM patients.

Late Presentation of COVID-19-Associated Transmural Myocardial Infarction with Non-Obstructive Coronary Atherosclerosis

Apresentação Tardia de Infarto Agudo do Miocárdio Transmural Sem Obstrução Coronariana Aterosclerótica Associado à COVID-19

Jaime Paula Pessoa Linhares Filho¹, Matheus Cardoso de Aragão², João Bosco Breckenfeld Bastos Filho¹, Ricardo Paulo de Souza Rocha¹, Fábio Holanda Lacerda¹, Francisco de Assis Carvalho de Santana¹

Introduction

There has been an increased incidence of coronavirus-associated thromboembolic events during the coronavirus disease 2019 (COVID-19) pandemic.¹ However, most cases presented with venous thrombotic events, mainly deep vein thrombosis and pulmonary thromboembolism,² whereas arterial and coronary phenomena are rare.³

Several pathophysiological factors can explain the relationship between COVID-19 infection and increased embolic phenomena. The main factors are increased inflammatory mediators, the release of prothrombotic factors, and endothelial dysfunction.^{4,5}

Cardiovascular presentations are also common in patients with COVID-19, such as atypical chest pain, dyspnea, arrhythmias, and myocardial injury with increased troponin levels.⁶ However, chest pain and increased troponin levels in the absence of coronary obstruction are rare and restricted to a few case reports.^{7,8} In addition, cardiovascular signs and symptoms associated with coronavirus infection occur in the acute stage of the disease with a symptomatic condition. Late presentation after complete symptom resolution is rarely reported.

Objective

Here we describe the case of a patient with the late presentation of chest pain associated with increased myocardial injury biomarkers after hospital discharge from a COVID-19 admission. The patient underwent coronary cineangiography and cardiac magnetic resonance imaging (MRI), and the syndromic diagnosis was myocardial infarction with non-obstructive coronary atherosclerosis (MINOCA). These results highlight the possibility of cardiovascular presentations in a subacute COVID-19 infection context.

Clinical case description

A 55-year-old man was admitted to the Emergency Department of our hospital with complaints of sudden-onset severe chest pain unrelated to exertion and was not treated with irradiation. The patient denied other associated symptoms.

Before this clinical condition, the patient had been admitted to an inpatient bed in our hospital for 13 days with the diagnosis of COVID-19 and had used a nasal oxygen cannula and the following medications: dexamethasone, codeine, colchicine, and prophylactic enoxaparin. One day after hospital discharge, he started complaining of chest pain.

A physical examination revealed a heart rate of 92 bpm, blood pressure of 122/80 mmHg, no significant changes on cardiac and pulmonary auscultation, good peripheral perfusion, and symmetrical pulses. His chest pain did not worsen with deep inspiration or palpation.

Personal history

The patient had a normal weight and no known risk factors or other diseases, nor was he regularly taking any medication. At the time of admission, he was no longer in pain.

Differential diagnosis

The following diagnostic hypotheses were proposed due to the recent COVID-19 infection and his clinical presentation: myocarditis, pericarditis, acute coronary syndrome, pulmonary thromboembolism, and Takotsubo syndrome.

Diagnostic investigation

After being admitted to the Emergency Department, the patient underwent a 12-lead electrocardiography (ECG) and troponin collection. The ECG showed sinus rhythm and an anterosuperior divisional block without changes suggestive of ischemia (Figure 1). The high-sensitivity troponin levels were: 555.7 ng/L, 1,038 ng/L, 1,029 ng/L, and 853.5 ng/L. The other biochemical tests showed no significant changes.

Transthoracic echocardiography (TTE) showed no segmental contractility or valve changes.

Next, as he reported feeling chest pain and his biomarker levels were increased, he underwent coronary angiography, which showed no significant coronary obstructions (Figure 2).

Based on the diagnostic hypothesis of myocarditis, a cardiac MRI was performed and showed an area of late transmural enhancement located in the apical region of the left ventricle compatible with acute myocardial infarction (Figure 3, Videos 1 and 2). The test was

Case Report

Figure 2 – Absence of significant coronary obstructions on coronary angiogram.

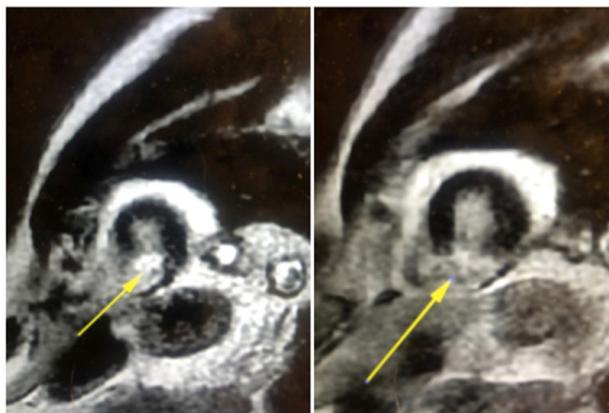

Figure 3 – Cardiac magnetic resonance images showing late transmural enhancement in the apical region of the left ventricle (yellow arrow).

performed 6 days after the event with no signs of high signal intensity on T2-weighted sequences suggestive of myocardial edema.

The coronary angiogram was reviewed by two interventional cardiologists. However, no coronary obstruction that could have gone unnoticed was identified.

Thus, the diagnostic hypotheses were ruled out due to absence of enhancement suggestive of myocarditis on cardiac MRI; the absence of electrocardiographic and

echocardiographic signs suggestive of pericarditis (as well as significant biomarker increase with chest pain not characteristic of pericarditis); the absence of electrocardiographic (sinus tachycardia and/or S1Q3T3 pattern) and echocardiographic signs (no right ventricular dysfunction and/or signs of pulmonary hypertension) suggestive of pulmonary thromboembolism; and the absence of echocardiographic segmental contractility changes suggestive of Takotsubo syndrome.

Accordingly, we started the patient on dual antiplatelet therapy and a statin. He developed no new symptoms and was discharged from the hospital.

Discussion

In this case, in the absence of coronary obstructions, ventricular dysfunction, and/or segmental contractility changes, the main diagnostic hypotheses were myocarditis and MINOCA. In this scenario, MRI was an essential differential diagnosis tool.⁹

After the complementary MRI findings, we believe that COVID-19-related factors may have influenced the formation of coronary thrombosis or distal emboli and resulted in the transmural pattern of late enhancement in the left ventricle.

In this sense, we observed a rare cardiovascular complication potentially associated with COVID-19 infection that has a temporally atypical clinical presentation. Thus, we must pay

attention to the possibility of late coronary events in COVID-19 patients and consider the possible persistence of inflammatory injury secondary to COVID-19 in the medium term. New studies may be necessary to identify the real incidence and clinical impact of these changes.

Dilated Cardiomyopathy as Initial Presentation of Mucopolysaccharidosis in Infant

Cardiomiopatia Dilatada em Lactente como Apresentação Inicial de Mucopolissacaridose

Introduction

Mucopolysaccharidoses are rare genetic diseases caused by decreased lysosomal enzymes that act in the catabolism of glycosaminoglycans, connective tissue extracellular matrix polymers. Glycosaminoglycans progressively accumulate in the airways, mucous membranes, lungs, bones, joints, heart, liver, eyes, ears, and central and peripheral nervous systems. The multiple affected organs characterize its multisystemic presentation with a wide spectrum of severity and clinical presentations. The most severe phenotype is Hurler syndrome (type I mucopolysaccharidosis), with an incidence of 0.61–1.30 per 100,000 live births.¹

The heart is affected in more than 50% of mucopolysaccharidosis cases,² with both valvular and myocardial involvement in addition to a possible association with systemic arterial hypertension (SAH).³

Specific treatment consists of enzyme replacement therapy (ERT), which, along with hematopoietic stem cell transplantation (HSCT), prolong the child's life and improves their symptoms, especially if started early.^{4–6}

Case report

Our patient was a male infant with a birthweight of 3,360 g and no perinatal complications. At eight months of age, he developed sweating during feedings, vomiting, and irritability. He was evaluated in the emergency room, where a chest X-ray showed remarkable cardiomegaly (Figure 1B). The patient had a previous history of a neuro-psychomotor developmental delay, recurrent respiratory infections, upper respiratory obstruction, hydrocephalus requiring ventriculoperitoneal shunt implantation, and recurrent bilateral inguinal hernia. The parents were young and non-consanguineous, and the couple's first child was stillborn without an identified cause.

At nine months of age, the patient was evaluated in a tertiary pediatric cardiology service and was already using captopril. He had persistent heart failure (HF) signs and

symptoms in addition to a weight-height deficit, weighing 8,880 g (Z-score: -2.44). A general examination showed several dysmorphisms such as infiltrated facies (Figure 1A), a high and narrow palate, gingival hypertrophy, a saddle nose, pectus carinatum, inguinal hernias, an umbilical hernia, an extensive Mongolian spot, a lumbar hump, bilateral diffuse corneal opacification, and a claw hand. A cardiovascular examination showed a regular heart rhythm without murmurs, a heart rate of 130 bpm, O₂ saturation of 98%, a systolic blood pressure of 120 mmHg (p: 99.93), a diastolic blood pressure of 60 mmHg (p: 99.74), a palpable liver at 5 cm from the right costal margin, and a non-palpable spleen.

Echocardiography (Figure 1C) showed a significantly increased left ventricle (LV) with a diastolic diameter of 42 mm (Z-score: 4.4) and a systolic diameter of 34 mm (Z-score: 5.6) in addition to diffuse hypocontractility with an LV ejection fraction (LVEF) of 39% and 42% by the Teichholz and Simpson's methods, respectively, and global longitudinal strain (GLS) of 13.7%. His right ventricular systolic function was slightly compromised, with a tricuspid annular plane systolic excursion of 10 mm (Z-score: -2.84) and lateral tricuspid annulus S' of 6.0 cm/s (Z-score: -3.60). The mitral and aortic valves had mild leaflet thickening without associated dysfunction.

The patient underwent pharmacological treatment for the HF and was referred for a genetic evaluation, which confirmed the diagnosis of type I mucopolysaccharidosis. His urine glycosaminoglycan level was 880 mcg/mg (reference range [RR], 133–274 mcg/mg). Glycosaminoglycan electrophoresis showed the presence of dermatan and heparan sulfate. Alpha-iduronidase (IDUA) levels of the plasma and leukocytes were reduced at 0.10 nmol/h/mg protein (RR, 6.6–34 nmol/h/mg protein) and 0.11 nmol/h/mg protein (RR, 27–71 nmol/h/mg protein), respectively. A molecular genetic analysis detected the W402X/W402X variant in both alleles of the IDUA gene. A radiographic evaluation showed dysostosis multiplex, ovoid vertebrae, paddle-shaped ribs, convergence of the proximal region of the metacarpals, a shallow acetabulum, and small ilia — signs compatible with the diagnosis of mucopolysaccharidosis.

Electrocardiography revealed sinus rhythm, a heart rate of 136 bpm, QRS complex axis at +60°, a PR interval of 80 ms, a corrected QT interval of 366 ms, T-wave inversions in D2 and D3, a deep Q wave at V6, and signs of LV overload.

ERT was instituted at 11 months of age with reduced liver volume, weight gain, improved general condition, reduced upper respiratory obstruction, and greater diet acceptance. At 12 months, HSCT was indicated, but the family refused to

provide consent. At 16 months of age, the infant presented with an infectious respiratory intercurrentence that resulted in acute decompensation of the treatment-refractory HF and culminated in death.

Discussion

Mucopolysaccharidosis is rare but associated with characteristic phenotypic findings that should arouse syndromic suspicion. A careful and detailed evaluation associated with knowledge of the disease presentation can lead to a suspected diagnosis that, once confirmed, is amenable to treatment that changes the natural course of the disease.^{5,7}

The reported patient had phenotypic characteristics of mucopolysaccharidosis such as infiltrated facies, palate changes, gingival hypertrophy, saddle nose, pectus carinatum, Mongolian spots, a lumbar hump, restricted knee and elbow mobility, claw hands, corneal opacity, inguinal hernias, and an umbilical hernia.

The cardiovascular system involves glycosaminoglycan deposits in structures such as the valvular endocardium, subvalvular apparatus, myocardium, conduction system, and vessels, especially the coronary arteries.³ This condition can cause conduction disorders, myocardial hypertrophy, valvular dysfunction, coronary heart disease, and sometimes SAH (Table 1).

The most common echocardiographic findings are mitral and aortic valve changes.² The leaflets are generally thickened, the mitral subvalvular apparatus involves shortened chordae tendineae, and the papillary muscles are thickened, possibly associated with valvular regurgitation or stenosis. Theodore *et al.* reported a case series that reiterated the findings of valvular changes in mucopolysaccharidosis.⁹ Myocardial dysfunction, in turn, is uncommon, but types I, II, and VI are correlated with more severe cardiovascular involvement³ and a worse prognosis. In the

case reported here, the valvular changes were mild and lacked repercussion, but there was a significantly reduced LVEF and GLS.

The conduction system may present a broad spectrum abnormality ranging from frequent sinus tachycardia to severe arrhythmias with a risk of sudden death. In the case studied here, the electrocardiographic changes were attributed to chamber dilation.

Even with pronounced glycosaminoglycan deposits in the myocardium, ventricular function is impaired in only a minority of patients. Davison *et al.* evaluated 29 children with type I mucopolysaccharidosis, reporting that five of them had dilated cardiomyopathy at the initial presentation. Similarly, Wiseman *et al.*⁴ studied a group of 44 children with type I mucopolysaccharidosis diagnosed in the first four months of life; of them, only six presented with severe dilated cardiomyopathy, with an LVEF of 15–40%. Hirth *et al.*⁵ also corroborated the rare onset of HF as the main mucopolysaccharidosis presentation and detected several mutations in their patients, including W402X/W402X, which was identified in the reported case. The ventricular function of all patients recovered after ERT or HSCT. However, the present case was diagnosed late and the patient's ventricular function was unable to recover prior to death due to infectious complications.

The presence of myocardial dysfunction of undefined etiology associated with phenotypic characteristics of mucopolysaccharidosis in infants should raise early diagnostic suspicion of the disease. The introduction of specific treatments and the management of several associated morbidities greatly impacts patient quality of life.

Diagnosis of Coronary Anomaly of the Circumflex Artery With Retroaortic Course by Transthoracic Echocardiography (Rac Sign) Confirmed by Computed Tomography Coronary Angiography: A Case Series

Diagnóstico de Anomalia Coronariana da Artéria Circunflexa com Trajeto Retroaórtico por meio do Ecocardiograma Transtorácico (RAC Sign) e Confirmação pela Angiotomografia de Artérias Coronárias: Série de Casos

Raul Serra Valério¹ , Alfredo A. Eyer Rodrigues^{1,2} , Carlos Eduardo Suaide Silva¹ , Marly Uellendahl MD, PhD^{1,2} , Luciano de Figueiredo Aguiar Filho^{1,3} 

¹Diagnóstico da América S/A (DASA); ²Federal University of São Paulo (UNIFESP); ³Dante Pazzanese Cardiology Institute (IDPC).

Introduction

Congenital coronary artery anomaly (CCAA) is a relatively rare condition with an estimated population prevalence of 0.21–5.79%.¹ CCAA presents a wide spectrum of variations and can be classified into origin and course, intrinsic, and termination anomalies.^{1,2} The CCAA with the highest prevalence is the anomalous origin of the circumflex artery (CxA) from the right coronary sinus (RCS) with an estimated prevalence of 0.3–0.8%.

CCAA usually travels along a retroaortic course and may present different originations, such as from a common ostium with the right coronary artery (RCA), from separate ostia in the RCS, or from the proximal segment of the RCA.^{2–4}

Although this anomaly is usually benign, i.e., with the characteristic of not causing symptoms, ischemia, or cardiovascular outcomes, numerous cases in the specialized literature associate this anomaly with episodes of angina, ischemia, and acute myocardial infarction. This infrequent progression is mainly associated with factors related to the coronary artery origin angulation to extrinsic compression caused by aortic root dilation and the presence of an intramural course in the aortic wall.^{5–10}

Transthoracic echocardiography (TTE) is a noninvasive and easily accessible tool that allows a limited assessment of some findings suggestive of CCAA.¹⁰ One of these findings is the retroaortic anomalous coronary sign (RAC sign), a signal proposed by Witt et al. in 2017.^{10–12}

The RAC sign is characterized by a hyperechoic tubular image located on the atrial face of the atrioventricular groove perpendicular to the aorta. This finding showed high sensitivity for the diagnosis; therefore, it has a high relationship with the presence of anomalous origin of the CxA from the RCS with a retroaortic course.^{10–12}

Manuscript received 11/11/2021; revised 11/25/2021; accepted 3/2/2022

DOI: 10.47593/2675-312X/20223502eabc271

On the other hand, coronary computed tomography angiography (CCTA) is a robust diagnostic tool in the anatomical assessment of the coronary tree and, therefore, the diagnosis of CCAA. As it is a noninvasive method with high temporal and spatial resolution, CCTA is currently considered the first-choice method for suspected CCAA as described in the 2010 appropriate use criteria for CCTA of the American Heart Association (AHA).^{4,13}

Compared to invasive coronary angiography (ICA), CCTA is superior for CCAA assessments, especially in cases of course anomalies involving the ostium and proximal third of the coronary arteries, intrinsic anomalies (myocardial bridging), and termination anomalies (fistulas). CCTA also stands out compared to ICA due to the possibility of a three-dimensional evaluation that allows the analysis of the close relationship between the coronary and other cardiac and non-cardiac structures, mainly the aortic root and pulmonary artery, extremely important data in the prognostic assessment of CCAA.

This case series aimed to demonstrate the agreement between the echocardiographic finding (RAC sign) and the noninvasive anatomical assessment by CCTA, its high sensitivity, and the assessment of the presence or absence of myocardial ischemia in the absence of obstructive atherosclerotic lesions.

Case Reports

Case 1

A 52-year-old man had a body mass index (BMI) of 27.3 kg/m², had dyslipidemia, was using a high-potency statin, and had a history of stable atypical angina and intermediate cardiovascular risk by the Diamond-Forrester classification. A stress test (ST) and three-dimensional transthoracic echocardiography (3D-TTE) were requested to complement the diagnosis.

The 3D-TTE showed preserved global and segmental systolic function (end-diastolic volume [EDV], 122 mL; end-systolic volume [ESV], 44 mL; left ventricular ejection fraction [LVEF], 64%) and global longitudinal strain (GLS; 18.6%) were within the normal range (Figure 1). The diastolic function parameters were preserved and the heart valves showed no significant anatomical or functional changes.

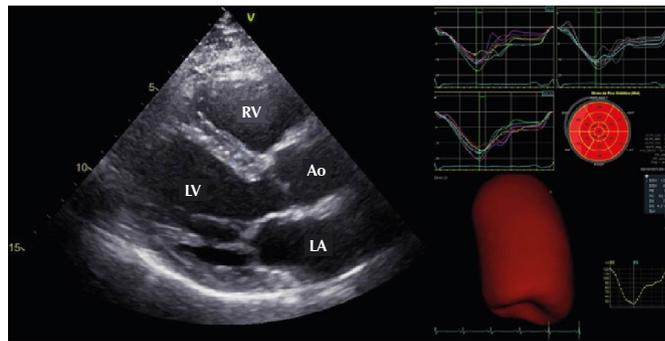

Case Report

However, a hyperechoic tubular image characteristic of the RAC sign was observed in the apical windows suggestive of a CxA anomalous retroaortic coronary course (Figure 2, Video 1).

The Bruce protocol was included in the ST and was effective and reached 99% of the age-predicted maximal heart rate. The patient presented no clinical symptoms on physical exertion and demonstrated excellent functional

capacity, adequate blood pressure behavior, and the absence of arrhythmias or electrocardiographic criteria for myocardial ischemia (Figure 3).

The CCTA findings complemented the diagnosis (Figures 4 and 5), corroborating the echocardiographic findings and showing an anomalous origin of the CxA from the RCS in a single ostium and at an acute angle (30°) traveling the

retroaortic course without signs of intramural course or extrinsic compression by the aortic root (aortic root with a maximum diameter of 32 mm). As for atherosclerosis, CCTA showed a 29 Agatston calcium score with atherosclerotic plaques in two segments of the coronary tree and no significant luminal reduction.

Case 2

A 53-year-old man who was asymptomatic had a BMI 28 kg/m², had dyslipidemia, and was using a high-potency statin came to our service for routine tests.

He underwent successful myocardial perfusion scintigraphy (MPS) with ST on a treadmill (Ellestad protocol), reaching the age-predicted maximal heart rate (Figure 6). The

patient presented no clinical symptoms, arrhythmias, or electrocardiographic changes suggestive of ischemia during the ST. MPS showed a preserved LVEF at rest (58%) and under stress (65%) and no perfusion defects.

The 3D-TTE presented cardiac chambers with preserved dimensions and normal global and segmental ventricular systolic function (EDV, 123 mL; ESV, 46 mL; and LVEF, 63%). GLS demonstrated preserved values (20.9%), while the diastolic function analysis findings were normal. No anatomical or functional valve changes were identified (Figure 7). The apical section showed a hyperechoic tubular image compatible with the RAC sign (Figure 8).

CCTA performed as a diagnostic complement identified an anomalous CxA origin from the RCS with a common ostium

with the RCA at an acute angle (35°) and with a retroaortic course. The course showed no luminal reduction and no signs of intramural course or extrinsic compression by the aortic root (maximum aortic root diameter, 33 mm) (Figures 9 and 10).

Case 3

A 31-year-old woman who had a BMI 20 kg/m², was asymptomatic, and had no known comorbidities was referred for routine TTE. The TTE showed preserved global and segmental biventricular systolic function. Her GLS (22.8%) and diastolic function were within the normal range. No significant anatomical and functional valve changes were identified. However, a hyperechoic tubular image was also visualized in apical sections perpendicular to the aorta, consistent with the RAC sign and suggestive of coronary anomaly (Figure 11, Video 2).

As a diagnostic complement, CCTA showed an anomalous origin of the CxA from the RCS in a separate ostium in an acute angle (26°), at a retroaortic course, and with no intramural course (Figures 12 and 13). No extrinsic compression by the aortic root was observed (largest aortic root diameter, 26 mm).

An atherosclerosis assessment presented a coronary calcium score of zero and absence of atherosclerotic plaques in the coronary segments.

In this case, no myocardial ischemia investigation was performed.

Discussion

Here we reported a series of three cases of a suspected CxA anomalous retroaortic course due to a TTE characteristic finding known as the RAC sign. Corroborating the data in the literature, this finding presented high diagnostic sensitivity since the coronary anomaly was confirmed in all cases on a noninvasive anatomical CCTA evaluation.

We also highlighted that CCTA is the gold standard method for CCAA evaluations since it is an easy and noninvasive way to analyze the characteristics of the coronary anomaly and provides important complementary information that can suggest a worse prognosis, such as the coronary ostium outflow angulation, the presence of an intramural course, and the relationship between the coronary artery and adjacent cardiac or non-cardiac structures.

Figure 11 – Apical four-chamber echocardiographic view showing tubular hyperechoic image – RAC sign (white arrow), suggestive of anomalous CxA origin with retroaortic course.

LV, left ventricle; RV, right ventricle. Source: Images obtained in the cardiovascular imaging sector of DASA S/A.

Video 2 – Four- and three-chamber apical view echocardiogram showing the retroaortic anomalous coronary sign (white arrow).

It is important to emphasize that an ST was performed in two of the cases described here to investigate myocardial ischemia. The results of both were negative, once again corroborating the findings in the literature, which mostly state that this anomalous course has a benign progression. However, as already mentioned, there are several reports of major and minor cardiovascular events related to this anomaly, a fact that supports the indication of ischemia research in cases of this diagnosed anomaly.

Conclusion

This case series highlights the fundamental role of TTE in the diagnostic confirmation of CCAA by the presence of the RAC sign, especially in cases with a retroaortic origin of the CxA. Despite the limitations inherent to the method, TTE has robust ability to identify this anomaly; thus, its use should always be considered so that a diagnostic opportunity is not missed.

Primary Cardiac Lymphoma: Role of Imaging Multimodality in Diagnosis

Linfoma Cardíaco Primário: o Papel da Multimodalidade de Imagem na Abordagem Diagnóstica

Abstract

Intracardiac masses are a diagnostic challenge since their symptoms can be common to cardiovascular pathologies. Some methods, whether invasive or not, enable differential diagnosis, histological confirmation, and adequate treatment. To better understand the importance of imaging multimodality and the approach to managing cardiac tumors, we investigated a case of a primary cardiac lymphoma in which the multidisciplinary approach allowed rapid diagnosis and treatment, including of intercurrents, with a promising initial response despite fatal progression due to severe acute respiratory syndrome coronavirus 2 infection.

Introduction

Intracardiac masses are a diagnostic challenge as their symptoms can be common to cardiovascular pathologies. Diagnostic methods, whether invasive or not, enable differential diagnosis, histological confirmation, and adequate treatment. To better understand the importance of imaging multimodality and the approach to managing cardiac tumors (CTs), here we report the clinical case of a patient with a mass in the right atrium (RA).

Case report

An 82-year-old woman with nonspecific symptoms was admitted for investigation on March 10, 2020. She denied any oncological history. The patient was emaciated, pale, eupneic, and hemodynamically stable. Laboratory tests showed mildly increased lactic dehydrogenase (LDH) and C-reactive protein (CRP) levels. It also demonstrated negative HIV and negative tumor marker serology. An electrocardiogram (ECG) revealed sinus rhythm with ventricular extrasystole. Computed tomography of the chest showed a dilated suprahepatic vena cava/right atrium (RA). The assessment was limited by the absence of contrast, with an axial diameter of 5.9 cm and no lymphadenopathy identified. Cardiac magnetic resonance

imaging (MRI) revealed RA enlargement and the presence of a mass measuring 3.7 × 1.5 cm in the proximal region of the superior vena cava (SVC). Heterogeneous perfusion and delayed enhancement were noted in addition to tissue characterization suggestive of a neoplastic origin (Figure 1A). Fluorodeoxyglucose (¹⁸F)FDG positron emission tomography CT (PET/CT) showed increased uptake in the para-caval and lateral RA region (maximum standardized uptake value, 18.8) (Figure 1B). Transesophageal echocardiography (TEE) showed a sessile echo-dense image with no cleavage plane on the RA wall close to the SVC outflow measuring 4.1 × 1.7 cm with subsequent endocardial biopsy (Figures 1C–E). A pathological examination identified high-grade B-cell non-Hodgkin's lymphoma and positive immunohistochemistry for BCL-2, Bcl-6, CD10, CD20 (Pan B), LCA (CD45), and Ki 67 (MIBI-1, positive in 95% of neoplastic cells) (Figure 2). The proposed treatment was cytoreduction with dexamethasone 20 mg for 4 days, followed by six cycles of R-mini-CHOP (rituximab 375 mg/m², doxorubicin 25 mg/m², vincristine 1 mg, cyclophosphamide 400 mg/m², and prednisone 60 mg from D1 to D5) with a 21-day interval and the first cycle divided into two stages. The patient presented with complete atrioventricular block (CAVB) on D4 for which a definitive pacemaker was indicated. She was discharged from the hospital after completing the first treatment cycle. Control TEE performed after two cycles of chemotherapy showed mass reduction (1.4 × 0.7 cm) with increased echo density (Figure 1F). She was readmitted on June 16, 2020 with respiratory failure due to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. Transthoracic echocardiography (TTE) showed no evidence of the mass in the RA, and she died on June 27, 2020.

Discussion

CTs are infrequent, while primary CTs (PCTs) are even rarer, with an incidence of 0.05% on autopsies, while metastatic tumors are 20–40 times more frequent. About 90% of PCTs are benign (myxomas, lipomas, fibroelastomas, etc.), while the other 10% are malignant, of which 95% are sarcomas and 5% are lymphomas and mesotheliomas. Primary cardiac lymphoma (PCL) represents 1.3% of PCTs, while a CT secondary to disseminated lymphoma occurs in 9–24% of cases.^{1–3} PCL is more frequent in women, especially in those after the fifth decade of life and those with immunocompromised status (acquired immunodeficiency syndrome or post-transplant immunosuppression).⁴

Clinical presentations are nonspecific, including chest pain, arrhythmia, congestion, pericardial effusion, SVC syndrome,

and sudden death.² Laboratory findings include leukocytosis, neutrophilia, increased erythrocyte sedimentation rate, CRP, LDH, β 2-microglobulin, and carcinoembryonic antigen. No single ECG finding is considered diagnostic, with ventricular or supraventricular arrhythmias and atrioventricular block being the most common. Chest radiography may show an increased cardiac area (mainly in the RA), pleural effusion,

and pulmonary congestion.³

Echocardiography allows the rapid noninvasive assessment of the PCL and is usually the initial approach. TTE has a sensitivity of 55–60%, while TEE reaches 97–100%. The PCL presents as a homogeneous infiltrative mass with a broad base located in the right cavities, predominantly in the RA, and can invade nearby structures. It usually presents with

pericardial effusion. The use of ultrasound contrast allows a differential diagnosis with non-vascularized masses (thrombi), as the presence of perfusion suggests malignant tumors (hypervascularity).⁵ CT assesses the extent of the mass and its relationship with cardiac and extracardiac structures, such as a low- or normal-density epicardial or myocardial infiltrative mass.^{3, 5, 6} On cardiac MRI, the lesions are poorly defined with delayed enhancement (unlike sarcomas that present with necrosis). Tissue characterization, a vascularization study, and the definition of myocardial and pericardial infiltration show the possibility of a cardiac tumor. PCL presents iso- or high-intensity signals on T2 and iso- or low-intensity signals on T1 images. Pericardial inversion-recovery images may show a high-intensity signal in the pericardial fluid suggestive of malignancy. Being located in the RA, having a diameter greater than 5 cm, the presence of a hemorrhagic pericardial effusion, and late enhancement are also suggestive of malignancy. Comparatively, MRI has higher sensitivity than CT (90–92% vs. 71–73%, respectively).³ Hypermetabolism on ¹⁸FDG PET/CT is suggestive of a malignant tumor.^{3,7}

A definitive diagnosis comes from the histological study of the mass or a cytological analysis of the pericardial fluid (positive in 2/3 of cases); a biopsy of the mass can be collected and analyzed by interventional (endovascular) or surgical cardiology.^{2,3} Diffuse B-cell lymphoma is the most common histological type (80% of cases), followed by follicular, Burkitt, and T-cell lymphoma.^{2,3} Surgical biopsy is chosen in cases of hemodynamic instability (cardiac tamponade, superior or inferior vena cava syndrome, and blood flow obstruction) and left-chamber tumors (to minimize embolic risk). In other situations, the endovascular biopsy can be guided by intracardiac or transesophageal echocardiography as in the case presented here.^{6,8}

Complete surgical resection is usually very difficult, being restricted to cases with great hemodynamic repercussions.⁹ The R-CHOP regimen, the most commonly used clinical treatment protocol, significantly impacts survival. Increased

complications such as arrhythmias, atrioventricular block, myocardial wall rupture, and death soon after the start of chemotherapy have been described. Of the proposed approaches to minimizing such risks, pre-treatment with corticosteroids and vincristine, a 50% reduction in the initial dose of cyclophosphamide and doxorubicin, and, more commonly, fractionation of the first cycle into two steps with a 15-day interval similar to what we did here, is required.^{4,10} The response is favorable in 79% of cases, with complete remission achieved in 59%.^{9,10} Treatment responses can be assessed as reduced tumor burden on echocardiography or MRI and by reduced metabolic activity on PET/CT.^{3,5,10}

PCL behaves aggressively, resulting in death in a few months when not properly treated. On the other hand, compared to other malignant tumors, it responds favorably to treatment with improved long-term survival.⁴ Immunodeficiency, extracardiac involvement, left ventricular involvement, and presence of arrhythmia are markers of a worse prognosis.⁴ Disease-free survival increased from 12 to 24 months after rituximab was included in the chemotherapy treatment.^{4,10}

Conclusion

Here we reported a case of PCL in which the multidisciplinary approach allowed rapid diagnosis and treatment, including intercurrentence, with a promising initial response despite fatal progression due to SARS-CoV-2 infection.
